In patients with localized cancer, there are few contraindications to this procedure. Patients with severe ankylosis of the hips or spine and those with unstable artificial hip replacements may not tolerate the exaggerated lithotomy position. However, common degenerative disk disease is not a contraindication to positioning. Some patients, such as those having renal transplantation or those with severe inflammation secondary to placement of synthetic mesh for repair of a hernia or the morbidly obese, who may not be amenable to RRP, typically may undergo prostatectomy by the perineal approach (Yiou et al, 1999; Boczek and Melman, 2003). Additionally, a large (>100 g) prostate and a narrow pelvis can cause difficulties with this surgical approach.

Preoperative Care and Position

A full bowel preparation is administered on the day before surgery on the basis of surgeon preference; the patient is instructed to consume polyethylene glycol or administer a Fleet Phospho-Soda enema in the afternoon before surgery. Also, 1 g of neomycin is administered orally at 12:00, 2:00, 4:00, 6:00, 8:00, and 10:00 PM. This bowel preparation allows primary closure of any inadvertent rectal injury at the time of surgery without problem. A sample for blood type and antibody screen is obtained from all patients in the days or hours before surgery, but because blood loss is minimal and transfusion rarely required, a crossmatch is unnecessary; also, preoperative donation and storage of blood by the patient is not required.

In the preoperative holding area, antithromboembolic surgical stockings are positioned and the patient is administered a second-generation cephalosporin intravenously. Although perineal prostatectomy lends itself to regional anesthetics such as spinal or epidural anesthesia, most patients receive a general anesthetic. The only specialized instruments needed are curved and straight Lowsley

Figure 114-39. The modified exaggerated lithotomy position. The perineum is only slightly elevated and almost at a 90-degree angle with the floor. The legs are positioned at nearly a 75-degree angle with the floor.

tractors, a self-retaining retractor such as the mini-crescent or Thompson, and a headlight.

After induction of anesthesia, the patient is positioned supine so that when the leg portion of the operating table is lowered, the buttocks are extended beyond the table edge. Allen stirrups are stationed 2 inches cranially on the rail so there is ample room for the attachment of the self-retaining retractor. The patient is then placed in an exaggerated lithotomy position with the perineum almost parallel to the floor or in a modified exaggerated lithotomy position with the perineum only slightly elevated (Fig. 114-39). The perineum, anus, and scrotum are shaved, and the abdomen inferior to the umbilicus, penis, scrotum, perineum, anus, and both thighs are painted with povidone-iodine in the standard sterile fashion. After gowning, a sterile towel is sewn from the 9-o'clock to the 3-o'clock position around the anus at the mucocutaneous pigmentation line with silk suture, maintaining a sterile environment. Leg and perineal drapes are placed. The upright of the self-retaining retractor is secured to the table rail on the patient's left while the sterility of the upright is maintained.

Exposure of the Prostate

A curved Lowsley tractor is placed transurethral into the bladder and its wings opened. A curvilinear incision is made from a position just medial to the right ischial tuberosity to a position just medial to the left ischial tuberosity. The incision should not extend posteriorly beyond the 3- and 9-o'clock positions relative to the anus. Blunt dissection is employed to open and develop each ischiorectal fossa lateral to the central tendon, and the central tendon is then divided by electrocautery (Fig. 114-40). In the original description by Young (1905), the dissection is carried anteriorly along the external anal sphincter until arriving at the rectourethralis muscle (1905). However, with the Belt approach (Belt, 1939), which we prefer, the fibers of the external anal sphincter are dissected and retracted anteriorly with an appendiceal retractor; these fibers are not incised (1939). The longitudinal muscle fibers of the rectum are identified, and gentle traction is placed dorsally on the rectum by a dampened sponge. The plane is developed leading to the rectourethralis muscle, which is formed by fascicles of the rectal muscle, connecting the rectum to the perineal body. It appears as a strap of muscle tenting the rectum ventrally. Without any traction on the Lowsley tractor, the rectourethralis muscle is divided close to the apex of the prostate with vertically oriented scissors, allowing the rectum to fall dorsally; caution must be exercised to prevent rectal injury at this point of the procedure. Gentle pressure is then applied on the Lowsley tractor toward the anterior

Figure 114-40. Each ischiorectal fossa is dissected bilaterally, and the finger is bluntly brought beneath the central tendon. The central tendon will be divided with electrocautery as traction is maintained with the finger.

Figure 114-41. The external anal sphincter is retracted anteriorly, and the rectourethralis muscle is divided. The prostate (P) is delivered into the field of view.

abdominal wall. This maneuver delivers the prostate well into the field of view and allows the blunt, digital dissection of the prostate from the rectum in a cephalad direction until the base of the prostate is identified at the vesicoprostatic junction (Fig. 114-41). Classically, the proper plane is between the anterior and posterior leaves of Denonvilliers fascia.

Nerve-Sparing Dissection

Resumed traction on the Lowsley tractor toward the anterior abdominal wall again brings the prostate into the incision. If preservation of the NVBs is intended, the exposed anterior layer of Denonvilliers fascia is incised vertically in the midline from the vesicoprostatic junction to the apex of the prostate with a No. 15 blade scalpel. Avoiding use of electrocautery, careful lateral dissection with gentle lateral traction preserves the NVBs as they course between the layers of Denonvilliers fascia at the posterolateral edge of the prostate. The fascia and enclosed nerves must be sufficiently mobilized to allow eventual extraction of the prostate without stretching or damage of the bundles.

Attention is then directed toward the prostatic apex and urethra. The Lowsley tractor can be palpated within the urethra, and a right-angled clamp is placed with the open points facing cephalad on either side of the urethra to dissect the NVBs away from the urethra as they course distally. The No. 15 blade scalpel is again used to incise the posterior aspect of the urethra over the Lowsley tractor (Fig. 114-42). The curved Lowsley tractor is then replaced by a straight Lowsley, and the wings are opened in a vertical fashion.

Figure 114-42. The anterior urethra is incised over the curved Lowsley tractor (L) between the membranous urethra (M) and prostate (P).

Figure 114-43. The urethra is divided, and the curved Lowsley has been replaced with a straight Lowsley tractor (L). The anterior prostate (P) has been dissected, and the puboprostatic ligaments are divided, exposing the bladder neck (BN).

With moderate traction on the Lowsley tractor, the remaining intact anterior aspect of the membranous urethra is sharply transected from the prostatic apex and the anterior prostate is freed to the bladder neck by sharp and blunt dissection.

The self-retaining retractor is attached to the previously placed upright, and blades are placed in the 3-, 9-, and 12-o'clock positions. Dissection is then directed over the anterior prostate from the apex toward the bladder neck. Traction on the Lowsley tractor aids in this portion by bringing the prostate into the incision. **The surgeon must be mindful not to dissect too far ventrally and to touch on the dorsal venous complex.** To sufficiently expose the anterior prostate, the puboprostatic ligaments are encountered and divided with scissors (Fig. 114-43).

The junction of the bladder neck and prostate base is then identified by palpating the wings of the Lowsley tractor. This junction is then further developed with blunt and sharp dissections, preserving the bladder neck. The bladder is entered anteriorly with a scalpel, the Lowsley tractor is removed from the urethra, and a long right-angled clamp is passed retrograde through the prostatic urethra and bladder neck. A 14-Fr red rubber catheter is then fed into the open right-angled clamp and pulled through the prostatic urethra; the ends are clamped together with a Kelly clamp, making a loop that may be used for manipulation of the specimen (Fig. 114-44). Traction on the catheter further delivers the prostate into the incision,

Figure 114-44. The bladder neck (BN) is incised, and a red rubber catheter is placed through the prostatic urethra (PU) and used to hold traction on the prostate (P).

and dissection of the anterior bladder neck is continued circumferentially around the prostate base. Identification of the ureteral orifices is generally unnecessary unless the dissection inadvertently involves the trigone. The lateral attachments and vascular pedicles are found coursing toward the base of the prostate and are dissected, sharply divided between right-angled clamps, and secured with 3-0 absorbable ties. To preserve the NVBs, the lateral pedicles should be divided close to the prostate, taking care not to compromise the surgical margin. Electrocautery is avoided during this phase.

The dissection is continued posteriorly at the bladder neck to separate it completely from the prostate. The red rubber catheter is then removed, and a right-angled clamp is passed along the midline posterior surface of the prostate with tips directed toward the base. The 14-Fr red rubber catheter is passed through the open tips of the right-angled clamp and pulled through, and the ends are secured together with a Kelly clamp, making a loop around the whole prostate. Traction then can be applied around the entirety of the prostate toward the incision, and an appendiceal retractor may be placed under the trigone, exposing the vasa deferentia and seminal vesicles (Fig. 114-45). Each vas deferens is grasped with a right-angled clamp, bluntly dissected, and divided with electrocautery. Each seminal vesicle is similarly grasped with a right-angled clamp, bluntly dissected, and divided, ligating the seminal vesicle artery with 3-0 absorbable ties. The complete surgical specimen is thus removed and passed off for pathologic examination.

Vesicourethral Anastomosis

On occasion, it may be necessary to reconstruct the posterior bladder neck with simple interrupted absorbable suture placed in a tennis racquet fashion. The ureteric orifices should be identified, and care should be taken to prevent damage to them.

The retractor placed at the 12-o'clock position is removed, and the red rubber catheter is placed retrograde through the penile urethra and clamped at the level of the glans so that traction can be applied to it while retaining it in the urethra. This catheter is used to identify and provide traction on the membranous urethra, enabling accurate anastomotic suture placement (Fig. 114-46). A 3-0 polyglycolic acid suture is placed from outside the anterior bladder neck at the 12-o'clock position and from inside to outside the membranous urethra at the same position and tied. While the assistant places traction on the red rubber catheter toward the contralateral side, the surgeon places sutures at the 2- and 10-o'clock positions. The red rubber catheter is removed, and a 22-Fr Silastic Foley catheter is carefully passed retrograde from the penile urethra and into the bladder. The 5-mL balloon is inflated with 15 mL of sterile water. Sutures are then placed at the 4-, 6-, and 8-o'clock positions and tied, completing the anastomosis.

Figure 114-45. The bladder neck is freed from the prostate, and a red rubber catheter is clamped around the entirety of the prostate (P). Further dissection at the prostate base exposes the right and left vas deferens (V) and bilateral seminal vesicles (S).

Figure 114-46. The specimen is removed from the field. A red rubber catheter emanates from the membranous urethra (M), and the bladder neck (BN) is open. The anterior aspect of the vesicourethral anastomosis (A) is complete. This exposure is unmatched with any other approach to radical prostatectomy.

Closure

The field is inspected for hemostasis and again for rectal injury. A Penrose drain is positioned near the vesicourethral anastomosis and brought through the incision. The levator ani is reapproximated with 2-0 absorbable sutures, avoiding damage to the NVBs and Penrose drain. The central tendon and Colles fascia are reapproximated, respectively, with 2-0 absorbable sutures; care must be exercised to use superficial "bites" posteriorly during this portion of the procedure because the anterior rectal wall is only a short distance away. The skin is closed with 4-0 absorbable suture interrupted in a vertical mattress fashion. The wound is dressed with a fluffed gauze dressing.

Postoperative Care

Patients are started on a clear liquid diet on the day of surgery and advanced to a regular diet as tolerated. Patients are encouraged to

ambulate routinely beginning the evening of surgery. Lower extremity sequential compression devices are used while the patient is in bed. **Rectal stimulation, instrumentation, and medication insertion are prohibited.** Furthermore, gentle irrigation of the catheter is performed only when absolutely necessary. The patient is provided oral analgesia and stool softeners. All patients are maintained on a prophylactic oral antibiotic until the catheter is removed. The Penrose drain is typically removed on postoperative day 1, and the urethral catheter is removed in the office 2 to 3 weeks after surgery, although it is recognized that earlier removal is feasible. **Patients are discharged on postoperative day 1 or 2** (Ruiz-Deya et al, 2001; Harris, 2003).

Pathologic Outcomes

RPP demonstrates excellent pathologic outcomes consistent with those of RRP. In a retrospective review, Korman and colleagues (2002) failed to demonstrate a significant difference in the incidence of positive margins between RPP specimens and those of RRP, 22% and 16%, respectively, and each had a 4% incidence of capsular incision. Furthermore, it has been shown that there is no significant difference in the time to PSA failure between patients who underwent RPP with complete excision of the seminal vesicles and those who underwent RRP (Theodorescu et al, 1998). A review of the literature demonstrates an incidence of positive margins of 15% to 44% of radical perineal specimens, with the prostate base being the most likely positive margin (Weldon et al, 1995; Iselin et al, 1999; Lance et al, 2001; Harris, 2003; Gillitzer et al, 2004). In the 20-year experience of Paulson, consisting of 1242 consecutive radical perineal prostatectomies for clinically organ-confined prostate cancer, 18% of patients with organ- or specimen-confined disease died either with or of prostate cancer. After 5 years, PSA failure (defined by PSA level > 0.5 ng/mL) occurred in 8%, 35%, and 65% of men with organ-confined, specimen-confined, and margin-positive disease, respectively. In patients with positive margins, the median time to PSA failure was 2.4 years; however, approximately 20% of patients with positive margins did not demonstrate biochemical failure. Cancer-associated death occurred approximately 10 years after the time of PSA failure (Iselin et al, 1999).

Morbidity

As a result of short operative times and relatively low blood loss, perioperative morbidity is low. Weldon and colleagues (1997) reported that 18% of their perineal prostatectomies experienced adverse events; however, most events were not serious, and no deaths were reported. Anastomotic strictures occur in 1% to 8% and usually within the first 4 months of surgery (Frazier et al, 1992; Levy and Resnick, 1994; Weldon et al, 1997; Gillitzer et al, 2004). Lower extremity neurapraxia, unique to the perineal approach, is often sensory and reported by Weizer and colleagues (2003) to occur in 25.5% of patients. **However, most series report an incidence of neurapraxia less than 2% and it is transient** (Weldon et al, 1997; Gillitzer et al, 2004). Keller (1999) reported a 0% incidence of neurapraxia in 284 prostatectomies and concluded that an operative time of less than 180 minutes is preventive. In experienced hands, **blood loss typically ranges from 200 to 800 mL and transfusions are necessary in approximately 5% of patients** (Weldon et al, 1997; Lance et al, 2001; Gillitzer et al, 2004). These rates of

transfusion are comparable with those of laparoscopic radical prostatectomy (Guillonnet et al, 2002; Rassweiler et al, 2003). Rectal injuries have been reported to occur during 1% to 11% of radical perineal prostatectomies (Parra et al, 1994, 1996; Levy and Resnick, 1994; Lassen and Kears, 1995; Weldon et al, 1997; Gillitzer et al, 2004). **When rectal injury is recognized at the time of surgery and repaired primarily with a two-layer closure, clinical sequelae are typically avoided.** If it is unrecognized or when it occurs in concert with postoperative urinary extravasation, a rectocutaneous or rectourethral fistula may develop. As with rectal injury, fecal incontinence occurs at a higher rate after RPP than after RRP. Bishoff and colleagues (1998) surveyed 227 patients 12 months after radical prostatectomy and reported that 18% of perineal patients had a new onset of fecal incontinence compared with only 5% in the retropubic group. In a prospective longitudinal assessment by Dahm and colleagues (2003), rectal urgency was the most common reported problem, and symptoms resolved over time; only 2.9% of patients reported involuntary stool leakage by 12 months after RPP. The exposure of the vesicourethral anastomosis generated with the perineal approach results in excellent continence outcomes. In a series of 220 cases, with incontinence defined as daily use of pads, Weldon and colleagues (1997) reported a 95% continence rate within 1 year, with younger age being a significant predictor of improved urinary continence. Yang and colleagues (2004) confirmed these results in a prospective study. **In studies comparing the outcomes of perineal prostatectomy and RRP, urinary continence was either improved by the perineal approach or not significantly different** (Parra et al, 1994; Bishoff et al, 1998; Gray et al, 1999; Sullivan et al, 2000; Lance et al, 2001). To date, studies comparing laparoscopic radical prostatectomy and perineal prostatectomy are not available. **A review of the literature demonstrates potency in 35% to 70% of patients after nerve-sparing RPP** (Lerner et al, 1994; Harris and Thompson, 1996; Weldon et al, 1997; Rabbani et al, 2000; Ruiz-Deya et al, 2001; Harris, 2003). At 24 months of follow-up, Weldon and colleagues (1997) reported 73% potency in 22 patients who had a bilateral nerve-sparing procedure and 63% potency in 28 patients who had a unilateral bundle preserved, although these results were not statistically different. Lerner and colleagues (1994) demonstrated unassisted potency in 22% of nerve-spared patients and an additional 30% who achieved vaginal penetration with pharmacotherapy.

Summary

The use of RPP for the treatment of localized prostate cancer has been facilitated by the emphasis on the identification of prostate cancer at earlier stages. This technique provides cancer control for localized prostate cancer similar to that with RRP.

KEY POINTS: RADICAL PERINEAL PROSTATECTOMY

- There are few contraindications to RPP.
- RPP demonstrates proved long-term cancer control.
- A nerve-sparing approach may be applied to RPP with excellent potency outcomes.
- RPP is renowned for rapid convalescence and overall low morbidity.

Robotic Salvage Prostatectomy

Laparoscopic Pelvic Lymph Node Dissection

Summary

EVOLUTION OF MINIMALLY INVASIVE LAPAROSCOPIC PROSTATECTOMY

In the late 1970s and early 1980s several detailed anatomic studies performed in fetal and adult cadavers provided important insights into the periprostatic anatomy, especially that of the dorsal vein complex (DVC) (Reiner and Walsh, 1979), the neurovascular bundle (NVB) (Walsh and Donker, 1982), and the striated urethral sphincter (Oelrich, 1980). These observations provided a more anatomic approach to radical prostatectomy for prostate cancer, resulting in a significant reduction in operative morbidity. Subsequently, the anatomic, nerve-sparing open radical prostatectomy maintained a central role in the management of localized prostate cancer for more than two decades.

It was not until 1997 that an attempt at a less invasive approach to radical prostatectomy was explored. Schuessler and colleagues performed the first successful laparoscopic radical prostatectomy (LRP) in 1997. In their series of nine patients, operative duration was lengthy (8 to 11 hours) and the length of hospital stay was on average 7.3 days (Schuessler et al, 1997). Although the authors concluded that cure rates with LRP appeared comparable with those in open surgery, they could not define any significant advantages. As a result, LRP was not widely adopted in the field of urology.

Advances in task-specific surgical instrumentation, optics, digital video equipment, and computer and robotic technology opened a new frontier for minimally invasive laparoscopic prostatectomy. These advances led urologists to revisit LRP, spearheaded by two centers in France that reported on their techniques and early results (Abbou et al, 2000; Guillonnet and Vallancien, 2000). Their stepwise surgical approach to LRP proved to be both reproducible and teachable, although the learning curve remained challenging. Operative times were in a more acceptable 4- to 5-hour range with reported overall positive margin rates of 15% to 28%. This work rekindled worldwide interest in LRP, and in the ensuing years surgeons at a number of centers throughout the world acquired the skills and experience to perform this technique. However, advanced laparoscopic skills were necessary to perform a proficient LRP, especially for suturing of the vesicourethral anastomosis.

Computer-assisted surgical devices using mechanical robotic arms were adopted for use with radical prostatectomy in part due to their ability to aid the surgeon in performing the challenging task of laparoscopic suturing. One such device, the da Vinci Surgical

System (Intuitive Surgical, Sunnyvale, CA) quickly became the dominant robotic surgical device in the field of urology. By incorporating sophisticated wristed technology at the terminal ends of the robotic instruments, this robotic system offered surgeons the ability to operate, dissect, and suture with the facility of a human wrist. In addition, the 10× magnified, three-dimensional (3D) image provided by the specialized stereo-endoscope lens and camera offered an unprecedented view of the operative field and periprostatic anatomy, far superior to the 2D view of conventional laparoscopy. The first-generation robotic platform, originally launched in the United States in 2000, allowed for the surgeons to control three robotic arms simultaneously, two arms for robotic instrumentation and a third arm for control of the stereo-endoscope and camera. The second-generation da Vinci S system, made available in 2006, incorporated high-definition image capability with an additional fourth robotic arm for grasping and retraction. Finally the latest-generation robot, the da Vinci Si HD, which was launched in 2009, offered two separate surgeon consoles allowing two surgeons to operate simultaneously, providing an opportunity for improved operative efficiency and training.

Since its introduction into the United States in 2000, robotic-assisted laparoscopic prostatectomy (RALP) has rapidly grown in popularity with surgeons and patients alike. With rapid dissemination of this robotic platform into large tertiary referral centers and community hospitals throughout the country, RALP has become the dominant surgical approach for radical prostatectomy in the United States. There have been considerable and ongoing debates about the merits of RALP versus open surgery by either the retropubic or perineal route. Issues with equipment expense, the learning curve for the surgeon and surgical team, and patient-related outcomes remain. **Nonetheless, RALP has virtually replaced LRP in the United States, and the overwhelming majority of new surgeons have adopted RALP as their preferred surgical approach for prostate cancer.** Thus it seems virtually certain that the use of RALP will continue to proliferate.

This chapter highlights some of the surgical advances for both LRP and RALP. Further, technical details for the surgical dissection and currently available data on oncologic and functional outcomes are presented with reference to comparative effectiveness with radical retropubic prostatectomy (RRP). Finally, the authors review the role of robotic salvage prostatectomy, laparoscopic pelvic lymph node dissection (PLND), and complications of minimally invasive prostatectomy.

PATIENT SELECTION

Indications and Contraindications

The indications for LRP and RALP are identical to that for open surgery (i.e., patients whose cancer is suspected to be clinically localized). Patients should have a pathologically confirmed cancer clinically confined within the prostate (stage T1 or T2) or a cancer that extends beyond the margins of the prostate (T3) but still seems amenable to surgical extirpation with a wide resection. Based on the 2013 Revised Best Practice Statement by the American Urological Association (AUA), radiographic staging with CT and bone scan is recommended only for patients with suspected locally advanced disease, Gleason score of 8 or greater or prostate-specific antigen (PSA) level greater than 20 ng/mL. Absolute contraindications to minimally invasive laparoscopic prostatectomy include uncorrectable bleeding diatheses and the inability to undergo general anesthesia because of severe cardiopulmonary compromise. Patients who have received neoadjuvant hormonal therapy or who have a history of prior complex lower abdominal and pelvic surgery such as partial colectomy, inguinal mesh herniorrhaphy, or prior transurethral resection of the prostate (TURP) pose a greater technical challenge because of distortion of normal anatomic landmarks and adhesions but are not an absolute contraindication to LRP and RALP. In patients with a history of prior laparoscopic extraperitoneal mesh herniorrhaphy, a transperitoneal approach may be preferred over the extraperitoneal approach because dense adhesions in the retroperitoneal space often make attempts at initial access to the space of Retzius challenging.

Morbidly obese patients pose additional challenges due to the potential respiratory compromise encountered when placing these patients in a steep Trendelenburg position, as well as the relatively limited working space and limitations of trocar size and instrumentation length. Patients with large prostate volumes (e.g., >80 g) can have longer operative times, more blood loss, and longer hospital stay than those with smaller glands; however, long-term urinary outcomes appear comparable (Levinson et al, 2008, 2009; Link et al, 2008). Salvage surgery after failure of primary treatment (e.g., radiation, brachytherapy, cryotherapy, high-intensity focused ultrasound) has been successfully reported in properly selected patients but should be approached with caution because of the attendant risks and complications (Kaouk et al, 2008; Boris et al, 2009; Chauhan et al, 2011; Kaffenberger et al, 2013; Yuh et al, 2014). As a result of the effects of prior local radiotherapy or ablation, the tissue planes surrounding the prostate and especially between the posterior prostate and anterior rectum are often fibrotic and obliterated, increasing the risk for inadvertent entry into the rectum during salvage surgery. As a result, patients undergoing salvage prostatectomy need to be counseled on the potential risk for rectal injury and intestinal diversion in addition to the higher incidence of impotence and incontinence compared with surgery in the primary setting. Further discussion regarding the nuances of salvage robotic prostatectomy can be found in the Surgical Techniques section of this chapter. **It is strongly advised that these more complex patient scenarios be avoided in a surgeon's early experience with LRP and RALP; however, these patient features are not by themselves absolute contraindications for a minimally invasive approach to prostatectomy** (Brown et al, 2005a; Erdogru et al, 2005; Singh et al, 2005; Stolzenburg et al, 2005; Kaffenberger et al, 2013).

INSTRUMENTATION

Instrumentation required for LRP and RALP depends on the chosen approach and model of da Vinci system being used (i.e., three- vs. four-arm robot) in the case of RALP. **Box 115-1** lists suggested instrumentation for LRP and RALP. For LRP, the AESOP 3000 robotic arm (Intuitive Surgical) may be used to stabilize and control the laparoscopic lens and camera by handheld remote control, voice activation, or foot pedal control. Alternatively, a surgical assistant can be used for this purpose. During RALP, the use of the da

BOX 115-1 Suggested Instrumentation for Laparoscopic and Robotic-Assisted Laparoscopic Radical Prostatectomy

LAPAROSCOPIC RADICAL PROSTATECTOMY

- AESOP 3000 Robotic arm (Intuitive Surgical, Sunnyvale, CA) (optional)
- Monopolar electrocautery scissors
- Monopolar electrocautery hook device
- Bipolar forceps
- Ultrasonic shears
- Maryland dissector
- Laparoscopic needle drivers (two)
- Suction-irrigation device
- 10-mm, 0-degree and 30-degree laparoscope lens
- Veress needle
- 5-mm trocars (three)
- 12-mm trocars (two)
- 20-Fr van Buren urethral sound
- 18-Fr urethral catheter
- Small and medium-large Hem-o-lok clips (Teleflex Medical, Research Triangle Park, NC)
- 0 polyglactin suture (GS21) for dorsal venous complex
- 2-0 polydioxanone suture for posterior reconstruction
- 3-0 poliglecaprone (Monocryl) double-armed suture for anastomosis

ROBOTIC-ASSISTED LAPAROSCOPIC PROSTATECTOMY

- da Vinci S or Si HD Surgical System
- Endowrist Maryland bipolar forceps or PK dissector
- Endowrist curved monopolar scissors
- Endowrist ProGrasp forceps
- Endowrist large needle drivers (two)
- InSite Vision System with 0-degree and 30-degree lens
- 12-mm trocars (two)
- 8-mm metal robotic trocars (three if using a fourth robotic arm)
- 18-Fr urethral catheter
- Small and medium-large Hem-o-lok clips (Teleflex Medical)
- 0 polydioxanone suture for dorsal venous complex
- 2-0 polydioxanone suture for posterior reconstruction
- 3-0 Monocryl double-armed suture for anastomosis

Vinci S or Si HD system allows the surgeon to control a total of four robotic arms, with one being the stereo endoscope. The operation begins by using a 0-degree stereo endoscope and controlling a grasping forceps in the left robotic arm (such as the Maryland curved bipolar forceps or plasma kinetic dissector) and the curved monopolar scissors in the right robotic arm. The fourth robotic arm controls the ProGrasp forceps (Intuitive Surgical), a large atraumatic blunt grasper for retraction and exposure of tissues. The surgeon then toggles between control of any two of the three working robotic arms at any given time to allow for greater autonomy and to achieve optimal exposure and dissection.

PREOPERATIVE PREPARATION

Bowel Preparation

As with open surgery, a preoperative mechanical bowel preparation with magnesium citrate may be used. However, many surgeons have patients use a Fleet enema alone on the morning of surgery. A broad-spectrum antibiotic such as cefazolin is administered intravenously 30 minutes before skin incision.

Figure 115-1. Operating room equipment and setup for robotic-assisted (A) and pure laparoscopic radical prostatectomy (B). (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Informed Consent

In addition to bleeding, transfusion, and infection, patients undergoing LRP and RALP must be aware of the potential for conversion to open surgery. As with open surgery, patients must be counseled on the risk for impotence, incontinence, incisional hernia, and adjacent organ injury (e.g., ureter, rectum, bladder, small bowel). The risks with general anesthesia must be presented to the patient because LRP and RALP cannot be performed under regional anesthesia. In addition, it is appropriate for the surgeon to discuss his or her overall operative experience with radical prostatectomy, specifically in addition to the laparoscopic or robotic approach, and provide a realistic forecast of cancer control, as well as return to normal urinary and sexual function on the basis of each patient's unique characteristics.

Operating Room Personnel

LRP and RALP require that the surgical team, including the scrub technician, circulating nurse, and surgical assistant(s), be fully trained and skilled in the instrumentation, operative setup, and technical steps of these minimally invasive procedures. Only one skilled assistant is generally required for these procedures, but a second assistant may be used if available to provide retraction of tissues. For RALP, it is important for the tableside assistant to have adequate training in not only basic laparoscopy but also specifically the mechanics, setup, and troubleshooting of the robotic system. The scrub technician is also an integral part of the operative team and must be versed in the wide array of laparoscopic and robotic instruments that may be used to accomplish this procedure. Finally, using an anesthesiologist who is versed in the nuances and physiologic effects of prolonged pneumoperitoneum is vital in the

success of this operation. Typical operating room equipment and setup for RALP and LRP are shown in [Figure 115-1](#).

Patient Positioning

After induction of general endotracheal anesthesia, the patient is placed in a supine position in steep Trendelenburg with arms and hands carefully tucked and padded at the sides with egg-crate padding to avoid injury to the median and ulnar nerves ([Fig. 115-2A to C](#)). Sequential compression stocking devices are placed on both legs and activated. The patient's legs are spread apart and supported by spreader bars to allow for access to the rectum and perineum. Alternatively, the patient's legs may be placed in stirrups in the low lithotomy position. The patient is then secured firmly to the table using heavy cloth tape and egg-crate padding across the chest to help prevent the patient from sliding when in the steep Trendelenburg position (see [Fig. 115-2D](#)). Fixed shoulder rests should be avoided because this can result in compression injury to the shoulders and brachial plexus when in steep Trendelenburg. Slight flexion of the table at the level of the hips may be required to properly dock the robotic arms; however, exaggerated flexion should be avoided so as to minimize the risk for femoral neuropathia (see [Complications](#) section). An orogastric tube and urethral catheter are placed to decompress the stomach and bladder, respectively. Careful padding of vulnerable body parts such as the hips, shoulders, knees, and calves is important to prevent pressure injury and neuromuscular complications (see [Complications](#) section).

Anesthesia Considerations

Both LRP and RALP require general anesthesia. Because the patient's arms are tucked at the side and difficult to access, establishing

Figure 115-2. Patient positioning for robotic-assisted radical prostatectomy. During positioning on the operating room table, the draw sheet and egg-crate padding are used to help secure the patient's hands and arms to the side in the neutral position, taking great care to protect from injury to the median and ulnar nerves (A to C). To prevent the patient from sliding when in the steep Trendelenburg position, heavy cloth tape and egg-crate padding are placed across the patient's chest (D).

accurate pulse oximetry, blood pressure cuff placement, and intravenous access is critical before final patient positioning. The anesthesiologist must be aware of the potential consequences of carbon dioxide insufflation and pneumoperitoneum, including oliguria and hypercarbia. Prompt adjustments in minute and tidal volumes may be required by the anesthesiologist in the event of rising end-tidal CO₂ levels and hypercarbia, which may lead to systemic acidosis if left uncorrected (Meininger et al, 2004). This is especially true in the early experience of a robotic surgeon and his or her team because operative times generally can be long. Likewise, adjustments in CO₂ insufflation pressures may be required by the surgeon to reduce the risk for continued hypercarbia.

Increased intraocular pressure can occur in patients in an exaggerated Trendelenburg position, but in patients undergoing RALP this does not appear to have any apparent clinical long-term consequence, at least in healthy patients. However, there may be an increased risk for corneal edema and abrasion, making it even more important for the anesthesiologist to maintain good eye lubrication and protection. Taken together, given the potential for prolonged surgical times with a patient in the steep Trendelenburg position, especially in a surgeon's early experience, it is important to recognize these unique complications and maintain excellent communication between the surgeon and anesthesia team throughout the operation.

SURGICAL TECHNIQUE

Robotic-Assisted versus Pure Laparoscopic Approach

Most of the principles and considerations for the surgical dissection are similar regardless of whether a pure laparoscopic or robotic-assisted approach is used. For RALP, the da Vinci Surgical System is a master/slave system with three components: surgical robot (also called the patient side cart), surgeon console, and video

KEY POINTS: PATIENT SELECTION, INSTRUMENTATION, AND PREOPERATIVE PREPARATION FOR LAPAROSCOPIC AND ROBOTIC-ASSISTED LAPAROSCOPIC RADICAL PROSTATECTOMY

- Regarding patient selection, it is strongly advised that patients with more complex anatomic challenges (e.g., large prostate size, large median lobe, morbid obesity, prior pelvic surgery, after radiation, after TURP) be avoided in a surgeon's early experience with LRP and RALP; however, these patient features are not by themselves absolute contraindications for a minimally invasive approach to prostatectomy.
- Having a skilled bedside assistant who is well versed in basic laparoscopy, but also specifically in the mechanics, setup, and troubleshooting of the robotic system, can greatly facilitate RALP procedures.
- Both surgeon and anesthesiologist must be aware of the unique physiologic effects of prolonged pneumoperitoneum with patients in the steep Trendelenburg position, including hypercarbia and acidosis, corneal edema, increased intraocular pressure, and neurapraxia and take proper steps to prevent such complications.

cart. For the purpose of this chapter and for simplicity, the technique using the four-armed da Vinci Si HD system is described. The robot is docked at the foot of the operating table between the patient's legs. The tableside assistant is responsible for docking/undocking the robot, suction-irrigation, retraction of tissues, passing sutures into the operative field, and robotic instrument changes. The surgeon is seated at the surgeon console, which provides a 3D, 10× magnified, high-definition operative view and allows the

surgeon to have complete control of all camera movements and three additional robotic arms. The surgeon's thumb and index or third fingers are inserted into master controls that allow natural hand and wrist movements to be precisely replicated by wristed instruments at the terminal ends of the robotic arms in real time.

Surgeons highly skilled in laparoscopy may find the robotic technology unnecessary and discover that they are equally as facile with pure laparoscopic suturing and dissection as with the robot (Guillonnet, 2005). Most surgeons, however, think robotic technology significantly facilitates suturing of the vesicourethral anastomosis and aids in other aspects of the surgical dissection such as achieving the critical angles of dissection required to optimize cavernous nerve preservation.

Other than setup of the operating room and surgical fields, there is little difference in the surgical technique between LRP and RALP. In general, the following discussion of technique and the pros and cons of various maneuvers and approaches apply to either surgical approach.

Transperitoneal Approach

The most common approach to LRP and RALP is the transperitoneal anterior approach in which after transperitoneal access and insufflation, the space of Retzius is immediately entered and the prostate gland, seminal vesicle, and vasa are dissected from an anterior approach. This is in contrast to the transperitoneal retrovesical (or posterior) approach in which the seminal vesicles and vasa are initially approached and completely dissected behind the bladder near the cul-de-sac *before* the space of Retzius is entered. The transperitoneal access and approach is favored by most surgeons over the extraperitoneal approach because of the greater working space and familiar landmarks of the pelvis. For the purposes of this chapter, the transperitoneal anterior approach will be primarily described, with brief mention of the extraperitoneal approach.

Abdominal Access, Insufflation, and Trocar Placement

For a transperitoneal approach, pneumoperitoneum is established using either a Veress needle inserted at the base of the umbilicus or an open Hasson technique. After initial trocar placement, CO₂ insufflation pressure in general is maintained between 12 and 15 mm Hg. Secondary trocars are then placed under laparoscopic view. For RALP, an example of a trocar configuration is shown in Figure 115-3A. A 12-mm trocar is initially placed slightly inferior to or above the umbilicus for insertion of the stereo endoscope. In a morbidly obese or very tall patient, infraumbilical camera placement may be preferable to gain the proper visual angle to view the prostate gland. Three 8-mm metal robotic trocars are used by the working robotic arms of the surgeon while the assistant provides retraction, suction, and irrigation and passes clips and sutures via the 12- and 5-mm trocars placed along the patient's right side. The surgeon controls camera movement by depressing a foot pedal and using brief, simultaneous arm movements to control camera positioning and rotation. Endoscopes with either angled (30-degree) or straight-ahead (0-degree) viewing are available and interchangeable at various portions of the procedure. In general, most surgeons use the 0-degree endoscope lens throughout the operation; however, some surgeons prefer to switch to the 30-degree down lens when approaching the bladder neck, NVBs, and apical dissection. Figure 115-3B depicts the trocar configuration for LRP. The surgeon stands at the patient's left side and operates through the two pararectus trocars while one or two assistants use the lateral-most trocars. The endoscope is held and controlled by an automated endoscopic system for optimal positioning (AESOP) robotic arm or surgical assistant through the periumbilical trocar.

Extraperitoneal Approach

For an extraperitoneal approach, a 1.5-cm incision is made at the level just beneath the umbilicus and dissection is carried out down through the anterior rectus sheath. Using blunt finger dissection, a

Figure 115-3. Trocar configuration for robotic-assisted laparoscopic prostatectomy (A) and laparoscopic radical prostatectomy (B).

Figure 115-4. Creation of working space for extraperitoneal pure laparoscopic or robotic-assisted radical prostatectomy using a trocar-mounted balloon dilator device. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

space is created immediately anterior to the posterior rectus sheath and underlying peritoneum. A trocar-mounted balloon dilator device (PDB Balloon, Covidien Autosuture, Mansfield, MA) is inserted into the preperitoneal space anterior to the posterior rectus sheath and advanced down to the pubis along the midline. Using a 0-degree, 10-mm endoscope inserted through the balloon trocar, approximately 500 mL of air is inflated to develop the space of Retzius under direct laparoscopic view (Fig. 115-4). Secondary

trocars are then inserted as described previously in the discussion of the laparoscopic view. The operation then proceeds in the exact manner as in the transperitoneal anterior approach.

Pros and Cons of Extraperitoneal versus Transperitoneal Approach

In a retrospective comparison between extraperitoneal and transperitoneal LRP, [Hoznek and colleagues \(2003\)](#) found that the mean operative time was shorter with the extraperitoneal approach (169.6 vs. 224.2 minutes, $P < .001$), with the greatest time saved during access to the space of Retzius. They suggested that time to full diet was less with the extraperitoneal versus the transperitoneal LRP approach (1.6 vs. 2.6 days, $P = .002$) because the peritoneum had not been violated and postoperative ileus was minimized. [Eden and colleagues \(2004\)](#) found a statistically significant advantage in operative time, hospital stay, and return of early continence favoring patients undergoing extraperitoneal versus transperitoneal LRP, postulating that earlier return to urinary control may be secondary to less bladder dissection and, perhaps, less bladder dysfunction compared with transperitoneal LRP. Most studies, however, found little or no difference in operative time and perioperative outcomes between transperitoneal and extraperitoneal approaches ([Cathelineau et al, 2004](#); [Erdogru et al, 2004](#); [Brown et al, 2005b](#); [Atug et al, 2006](#)).

With an extraperitoneal approach, the simultaneous laparoscopic management of concurrent inguinal hernias using prosthetic mesh is feasible ([Stolzenburg et al, 2003](#)). Simultaneous inguinal herniorrhaphy has also been reported during transperitoneal LRP ([Allaf et al, 2003](#)); however, proper coverage of the mesh prosthesis is necessary using peritoneal flaps, omentum, or a second absorbable mesh to reduce the risk for direct contact between the mesh and bowel with subsequent fistula. The extraperitoneal technique may be preferable in patients with previous extensive abdominal surgery or morbid obesity. With the extraperitoneal approach, the peritoneum acts as a natural barrier, minimizing the potential for bowel injury and preventing the bowels from falling into the operative field and obscuring the surgeon's view. Furthermore, this approach helps confine any urine leak that may occur from the vesicourethral anastomosis within the extraperitoneal space. One limitation with the extraperitoneal approach is the reduced working space compared with the relatively larger working space of the peritoneal cavity gained with transperitoneal access. This is especially relevant when a well-meaning assistant attempts to clear the operative field of blood or smoke. Suctioning can evacuate CO₂ and rapidly collapse the already limited extraperitoneal working space, thus significantly compromising visualization. A second limitation to the extraperitoneal approach is in patients with a history of laparoscopic extraperitoneal mesh herniorrhaphy because the retropubic space is often obliterated, making attempts at extraperitoneal access challenging. Finally, higher CO₂ absorption has been reported with extraperitoneal versus transperitoneal insufflation, requiring a higher minute volume to compensate for hypercarbia and associated acidosis ([Meininger et al, 2004](#)). Overall, whether to use an extraperitoneal or transperitoneal approach for LRP or RALP is largely a matter of surgeon preference and experience and there is no consistently demonstrated advantage for either approach.

Developing the Space of Retzius

After abdominal access and trocar placement for the transperitoneal anterior approach, the pelvic contents are inspected ([Fig. 115-5](#)) and adhesions are lysed if present. The initial step is entry and development of the space of Retzius. The bladder is dissected from the anterior abdominal wall by dividing the urachus high above the bladder and incising the peritoneum bilaterally immediately lateral to the medial umbilical ligaments using monopolar scissors. The presence of prevesical fatty alveolar tissue confirms the proper plane of dissection within the space of Retzius. Applying posterior and

Figure 115-6. Division of urachus and entry into the space of Retzius. Cephalad traction on the urachus with the left hand helps identify the fatty alveolar tissue immediately anterior to the bladder, which marks the proper plane of dissection. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

cephalad traction on the urachus, the retropubic space is rapidly developed with a combination of blunt and sharp dissection along the relatively avascular plane ([Fig. 115-6](#)). Lateral dissection of the bladder is carried out down toward the crossing of the medial umbilical ligaments and vas deferens to ensure optimal mobility of the bladder, which minimizes tension when accomplishing the vesicourethral anastomosis. The fat overlying the prostate is removed using sharp dissection and electrocautery as needed, and the superficial branches of the DVC coagulated using bipolar electrocautery.

At this point, visible landmarks include the anterior aspect of the bladder and prostate, puboprostatic ligaments, endopelvic fascia, and pubis ([Fig. 115-7](#)). The endopelvic fascia and puboprostatic ligaments are sharply divided, exposing levator muscle fibers attached to the lateral and apical portions of the prostate. These fibers are meticulously preserved and bluntly dissected from the surface of the prostate exposing the deep DVC and urethra at their confluence with the apex of the prostate. Electrocautery is avoided if possible to minimize thermal damage to the external sphincter and nearby NVBs.

Accessory pudendal arteries traveling longitudinally along the anteromedial aspect of the prostate are easily recognized during LRP and RALP. Attempt at preservation of these arteries is important for erectile function because in some men these arteries may be the

Figure 115-7. Retropubic view of the bladder and prostate after entry into the space of Retzius. The fatty tissue overlying the anterior aspect of the prostate has been removed, exposing the puboprostatic ligaments, superficial and deep dorsal venous complex, and endopelvic fascia. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

dominant source of arterial blood supply to the corpora cavernosa (Nehra et al, 2008). These accessory arteries can usually be preserved, although separation of the artery from the prostatic apex and deep DVC can be somewhat challenging.

Ligation of the Deep Dorsal Venous Complex

As with open surgery, different methods have been described for control of the deep DVC. A common observation, though, is that the profuse bleeding, which is sometimes encountered during open surgery, is less apparent because of the tamponade effect on venous bleeding offered by the pneumoperitoneum even when the DVC is inadvertently entered. During RALP, the ProGrasp forceps can be used for fixed cephalad retraction of the prostate and bladder to achieve optimal exposure of the DVC and prostatic apex before DVC ligation. Similar retraction can be applied by the surgical assistant during LRP. The deep DVC is suture ligated using a 0-polydioxanone suture or polyglactin suture as close to the pubis and as far from the prostatic apex as possible (Fig. 115-8). Securing the deep DVC as far distal from the prostatic apex as possible can help minimize iatrogenic entry into the prostatic apex during later division of the DVC. For this reason, it is our opinion that the puboprostatic ligaments should be completely divided before ligation of the DVC to allow for adequate exposure and access to the most distal portion of the DVC as it traverses beneath the pubic symphysis. The needle is passed beneath the DVC and anterior to the urethra.

An alternative method to DVC ligation is the use of a laparoscopic linear stapling device, which ligates and divides the DVC in one step (Ahlering et al, 2004b; Nguyen et al, 2008). With most techniques, the DVC is not divided until later in the operation and immediately before prostatic apical dissection and division of the urethra. A back-bleeding suture may be placed along the anterior base of the prostate to help identify the contour of the prostate and aid in subsequent bladder neck identification and transection.

Figure 115-8. Ligation of the deep dorsal venous complex. A suture is passed from right to left, ligating the dorsal vein as distal as possible from the apex. Inset demonstrates the proper passage of the needle immediately anterior to the urethra. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Bladder Neck Identification and Transection

Proper identification of the bladder neck during RALP and LRP can be initially challenging because of the lack of tactile feedback in delineating the precise margin between the prostate and bladder. Several maneuvers are helpful in identifying the proper plane of dissection and in minimizing inadvertent entry into the base of the prostate. First, visual identification of the point of transition of the prevesical fat to the anterior prostate can serve as a guide. Second, intermittent and repetitive caudal retraction of an inflated urethral catheter balloon can help identify and confirm the transition between bladder neck and prostate. Note that any deviation of the balloon away from the midline signifies the likely presence of a median lobe of the prostate. Third, using a forceps to grasp and retract the dome of the bladder in a cephalad direction results in tenting of the bladder neck at its attachment to the prostate. Finally, further confirmation of this margin between the bladder and prostate is made by a bimanual palpation or pinch of the bladder neck using the tips of two robotic or laparoscopic instruments.

The anterior bladder is divided horizontally using monopolar scissors along the midline until the urethral catheter is identified. The anterior bladder neck incision should not be carried too far laterally because branches of the bladder pedicle are often encountered, resulting in unwanted bleeding. The balloon is decompressed, and the tip of the urethral catheter is brought through the bladder neck opening and lifted anteriorly with the assistant applying countertraction externally at the penile meatus to “suspend” the prostate.

The posterior bladder neck is inspected for the presence of a median lobe and to locate the ureteric orifices. If a vertical drop-off of the posterior bladder neck mucosa is noted, this often suggests the absence of a median lobe. Alternatively, if a mass effect from a large median lobe is identified, it may be delivered out of the bladder by anterior retraction with a ProGrasp forceps. However, further exposure by a transverse or sagittal cystotomy may be required to visualize beneath the protruding median lobe and identify the posterior bladder neck. The posterior bladder neck is horizontally divided with monopolar scissors, staying again along the midline to avoid bleeding from the lateral pedicles (Fig. 115-9). Dissection is carried out in a 45-degree downward angle to avoid entry into the base of the prostate or creating a buttonhole in the posterior wall of the bladder. In case of a prior TURP, the bladder neck margin is

Figure 115-9. Division of the posterior bladder neck. An assistant or ProGrasp forceps is used to grasp and elevate the urethral catheter anteriorly, providing exposure to the posterior bladder neck. Dissection is carried out along the midline, avoiding bleeding from the lateral pedicles. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

less evident and often distorted as a result of prior resection and scarring. Careful inspection is made of the posterior bladder neck, paying specific attention to the location of the ureteric orifices because they are often found close to the posterior bladder neck margin. Attempt at bladder neck sparing should be avoided in post-TURP and median lobe cases. When in doubt, the posterior bladder neck should be divided slightly more proximally in these particular cases so as to avoid inadvertent entry into the prostate gland with a resultant positive bladder neck margin.

Dissection of the Seminal Vesicles and Vasa Deferentia

After bladder neck transection, the seminal vesicles and vasa deferentia are individually identified, dissected, and divided, minimizing electrocautery if possible to prevent damage to the nearby NVBs (Fig. 115-10). One unique distinction between the transperitoneal anterior and retrovesical approaches is in dissection of the seminal vesicles and vasa deferentia. During a transperitoneal retrovesical approach, the initial step of the operation is complete dissection of the vasa deferentia and seminal vesicles deep within the cul-de-sac. After abdominal access, the vasa are dissected from lateral to medial toward their confluence at the ejaculatory ducts. The seminal vesicles are found immediately lateral to the distal portion of the vasa and are dissected free from the nearby NVB using hemoclips while avoiding the use of thermal energy (Fig. 115-11). With the dissection of the seminal vesicles and vasa now completed under excellent vision, these structures are simply grasped and brought through the opening once the bladder neck is divided from the prostate base. This retrovesical approach to the seminal vesicles and vasa deferentia is particularly useful in cases of a median lobe in which identification and dissection of these structures by the anterior approach may be more challenging because of the physical presence of the protruding median lobe in addition to the presence of urine and blood in the operative field.

Development of the Plane between the Prostate and Rectum

Separation of the posterior prostate from the anterior rectal wall is a key surgical maneuver to avoid rectal injury but also permit adequate identification of the prostatic pedicles and establish the medial border of the NVBs. Development of this plane in an antegrade fashion is a maneuver often unfamiliar to surgeons experi-

Figure 115-10. Dissection of seminal vesicles and vasa deferentia via the transperitoneal anterior approach. The seminal vesicles and vasa are identified and dissected within the opening created between the posterior bladder neck and prostate following division of the bladder neck. Hemoclips are used in lieu of electrocautery to avoid thermal injury to the nearby neurovascular bundles (NVBs). (Copyright Li-Ming Su, MD, University of Florida, 2009.)

enced with open surgery but one that is rapidly adaptable to laparoscopic and robotic approaches. Anterior retraction of the vasa deferentia and seminal vesicles by a surgical assistant or the robotic ProGrasp forceps helps with identification of the proper plane for the initial dissection (Fig. 115-12).

The Denonvilliers fascia is an inferior extension of the peritoneal cul-de-sac that lies between the prostate and rectum. With an intrafascial or interfascial dissection, Denonvilliers fascia can be separated from the posterior prostate by careful blunt and sharp dissection. The separation can be carried all the way to the prostatic apex and laterally to the medial aspect of the prostatic pedicle. The proper surgical plane is relatively avascular. When a wider margin of tissue is desired along the posterior aspect of the prostate, such as in cases of palpable disease, Denonvilliers fascia should be sharply incised just posterior to the junction of the seminal vesicle and prostate. This allows immediate entry into the anterior perirectal fat plane of dissection. Good visualization can be achieved as the dissection proceeds distally toward the apex staying between Denonvilliers fascia anteriorly and the anterior propria fascia of the rectum posteriorly.

Substantial bleeding typically suggests that the dissection may be too close to the prostate. If difficulty is encountered in establishing the proper plane of dissection, a new attempt can be directed to one side or the other of the initial entry point. Once the proper plane is entered, the dissection characteristically progresses rather smoothly by blunt dissection. The rectal wall should be mobilized far enough laterally and distally that there is sufficient separation for dissection of the NVB and prostatic apex.

Prostatic Pedicle Control

Various methods have been described for control of the prostatic pedicle. Some techniques use pure electrocautery, either monopolar or bipolar. Because of the propagation of thermal energy through tissue, which may result in damage to the nearby NVB, limitation of the use of electrocautery is advised and if possible avoided

Figure 115-11. Dissection of the seminal vesicles and vasa deferentia via the transperitoneal retrovesical approach. The vasa and seminal vesicles are identified as the initial step in this approach deep within the retrovesical space. The neurovascular bundles (NVBs) are dissected off of the seminal vesicles in an antegrade direction from the tip toward the base using hemoclips. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Figure 115-12. Development of the plane between the prostate and rectum. As the assistant or ProGrasp forceps is used to apply anterior traction on the seminal vesicles and vasa deferentia and downward traction on the rectum, a transverse incision is made in Denonvilliers fascia below the seminal vesicles, and blunt dissection is used to develop a plane between the posterior prostate and the rectum. *Inset* demonstrates the direction of dissection toward the prostatic apex without electrocautery. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

during division of the prostatic pedicle. Locking polymer Hem-o-lok clips (Teleflex Medical, Research Triangle Park, NC) are commonly employed, but engagement of the clipping mechanism does require good proximal and distal delineation and thinning of the pedicle tissue so that the clipping mechanism will engage. This is best facilitated by adequate mobilization of the rectum and lateral prostate for identification of the prostatic pedicle. Application of a temporary bulldog clamp to the pedicle with subsequent suturing of the pedicle after the prostate specimen has been removed also has been described (Ahlering et al, 2005; Gill et al, 2005). Regardless of the method used, though, successful division of the prostatic pedicle in the correct anatomic location is an important step in avoiding positive margins and damage to the nearby NVB.

Preservation of the Neurovascular Bundle

Preservation of the periprostatic parasympathetic nerve fibers important for erectile function is one of the key and most difficult maneuvers during radical prostatectomy, regardless of surgical approach. Increasingly, it is recognized that the periprostatic nerves of significance have a more diffuse and highly variable course than previously thought (Costello et al, 2004; Takenaka et al, 2004; Lunacek et al, 2005), but there is a confluence of nerves along the posterolateral aspect of the prostate commonly thought to be the predominant NVB. Nerve tissue extends posteriorly around the prostate, forming a virtual hammock of nerves. In addition, nerve fibers can be identified in the periprostatic tissue along the more anteromedial portion of the prostate gland, although there is still debate about their relative function and contribution to penile erections. A well-performed, nerve-sparing radical prostatectomy takes all of these considerations into account and preserves as much periprostatic nerve tissue as possible both from a qualitative and quantitative standpoint.

The superb visualization of the periprostatic tissues with laparoscopic surgery has led to a greater appreciation of the periprostatic fascial layers. Although there is some confusion in the literature regarding the terminology used for the various fascial layers, an *extrafascial* dissection typically implies dissection laterally between the lateral prostatic fascia and the levator fascia and posteriorly between Denonvilliers fascia and the anterior propria rectal fascia. An *interfascial* dissection is carried out laterally between the prostatic fascia and the levator fascia and posteriorly between Denonvilliers fascia and the posterior surface of the prostate (Fig. 115-13). This is the preferred approach in patients with presumed

Figure 115-13. Cross section of the prostate demonstrating the periprostatic fascial planes with respect to the location of the neurovascular bundles (NVBs). The *dashed line* indicates the direction of interfascial dissection (i.e., between the levator and prostatic fascia) to accomplish a high anterior release of the NVB from the prostate and establish the lateral NVB groove. The *solid line* indicates the incision made for a standard release of the NVB. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Figure 115-14. Entering into the interfascial plane of dissection for neurovascular bundle (NVB) preservation. The levator fascia is first incised along the anteromedial aspect of the midprostate, allowing entry into the interfascial plane of dissection. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

organ-confined disease because it permits safe preservation of the cavernous nerves without violating the anatomic limits of the prostate gland and capsule. Historically the periprostatic vasculature within the interfascial space has been used as a macroscopic landmark and visual surrogate for identifying and preserving the cavernous nerves. Patel and colleagues (2012) suggested that a dominant periprostatic artery specifically can be identified in 73% of cases during RALP and can serve as a consistent landmark for cavernous nerve preservation. Finally an *intrafascial* dissection is carried out between the prostatic capsule and the prostatic fascia and leaves virtually no periprostatic tissue overlying the prostate. Although technically feasible, this approach risks a higher incidence of positive margins because of the relatively closer dissection to the prostate gland. Even though these fascial layers as described do have some true integrity for intraoperative identification, it is also well recognized that they can be multilayered.

Damage to the NVB can occur because of direct incision, entrapment in a suture or clip, thermal injury, or traction. Some surgeons advocate release of the NVB from the prostate before mobilization of the specimen to help avoid traction injury. With the antegrade approach typically used for LRP and RALP, identification and at least partial release of the NVB along the lateral aspect of the prostate before controlling the prostatic pedicle can help drop the neurovascular tissue away from the gland and permit a more precise placement of hemoclips on the pedicle while preventing inadvertent entrapment of the nerve bundles. To accomplish this, the levator fascia is first incised sharply along the anteromedial aspect of the middle of the prostate entering into the interfascial plane of dissection (Fig. 115-14). Blunt dissection is carried out along the prostatic fascial plane gently dissecting the NVB off of the prostate in a posterolateral direction, thus partially releasing the NVB and developing a visible NVB groove. This groove serves as a visible landmark for precise hemoclip placement and division of the prostatic pedicle while avoiding entrapment of the NVB (Fig. 115-15). The ergonomics and scaled motion of the wristed robotic instruments are helpful in achieving this delicate dissection. During LRP, specially designed fine-tipped (0.8 mm) dissectors have been described to aid in NVB dissection and preservation (Su et al, 2004). Some discussion and debate has centered on how far anteriorly on the prostate the interfascial dissection of the nerve bundles should be performed. Whether high release (vs. standard release) of the NVBs preserves important nerves or simply allows for a physical handle to permit more precise, meticulous

Figure 115-15. Developing the interfascial plane of dissection. Using blunt dissection, the nerve bundle is partially released from the prostate in a posterolateral direction, forming a visible lateral neurovascular bundle (NVB) groove. This step serves to delineate the prostatic pedicle and course of the nerve bundle and allow for precise placement of hemoclips, while avoiding nerve entrapment. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

dissection and preservation of the true cavernous nerves located at the 5- and 7-o'clock positions without direct manipulation of these main nerve fibers is uncertain (see Fig. 115-13). However, there is a general consensus that thermal energy should be minimized and, ideally, completely avoided during dissection of the NVB. These microscopic parasympathetic nerve fibers are highly susceptible to thermal injury, as shown in both animal and human studies (Ong et al, 2004; Ahlering et al, 2005). Bleeding along the NVB is relatively minimal and may require no specific hemostatic measures. There may be small arteries or larger veins that require suturing with small tissue bites to avoid entrapment of adjacent nerves.

Patients with extremely large prostate glands (especially those >100 g) offer a unique challenge during preservation of the NVB. Maneuvering a large prostate gland in the tight confines of the bony pelvis can be challenging, especially during exposure of the prostatic pedicles and NVB. Effective exposure of tissues by the surgical assistant, as well as the fourth robotic arm, is critical in such cases.

Apical Dissection

The prostatic apex is a common location for tumor involvement and the most common site of positive margins with radical prostatectomy. Further, the steps required for apical dissection are crucial to preservation of erectile function and avoidance of urinary incontinence. The visualization of the operative field and the ability to limit bleeding from the deep DVC facilitate apical prostatic dissection during LRP and RALP.

Up to this point in the operation, antegrade dissection has permitted complete mobilization of the lateral, base, and posterior prostate, leaving division of the deep DVC and urethra from the prostatic apex for last. It is critical to avoid entry into the anterior prostate during division of the deep DVC because this may result in an iatrogenic positive margin. Although the previously placed DVC stitch may become dislodged or divided during this step, further sutures to secure the deep DVC can be easily placed. Also, bleeding from the deep DVC during attempts at resuturing can be kept to a minimum by transiently increasing the CO₂ insufflation pressure to 20 mm Hg to improve the tamponade effect on venous bleeding. Once the DVC is divided, there should be good visualization of the prostatic apex and its junction with the urethra (Fig. 115-16). The anatomy of the prostatic apex is variable and should be carefully inspected before division of the urethra. As much

Figure 115-16. Division of urethra. After division of the deep dorsal venous complex, the anterior and posterior urethra is divided sharply without electrocautery. A small rim of urethra may be safely left on the prostate apex to avoid an iatrogenic positive apical margin. Great care must be taken to avoid damage to the nearby nerve bundles. NVB, neurovascular bundle. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

urethral length as possible should be maintained, but an overlying anterior lip of prostate must be recognized, as well as posterior extension of prostatic tissue beneath the urethra. Nevertheless, leaving a small rim of urethra along the prostatic apex may be advisable to reduce the incidence of apical positive margins because this does not appear to have an adverse effect on the return of urinary continence (Borin et al, 2007). Sharp dissection with limited use of electrocautery is preferred during the prostatic apical dissection and division of the urethra, to prevent thermal injury to the external striated sphincter and nearby NVBs.

Intraoperative Inspection of Prostate

On completely freeing the prostate gland and before entrapment of the specimen, the entire surface of the gland can be inspected laparoscopically to assess the adequacy of resection and integrity of the tissues covering the prostate specimen. If concern exists regarding a close surgical margin, additional tissue may be excised specific to the location of concern; however, with experience this should rarely be necessary.

Pelvic Lymphadenectomy

It is generally at this time that pelvic lymphadenectomy takes place, because prior mobilization of the bladder allows for excellent exposure of the obturator lymph node region and iliac vessels. The extent of pelvic lymphadenectomy remains controversial but can be tailored on the basis of patient-specific risk factors, including PSA, clinical stage, and Gleason score. Technical description of a standard

versus extended laparoscopic pelvic lymphadenectomy follows later in this chapter.

Entrapment of Specimens

The prostate and pelvic lymph nodes are entrapped within a 10-mm laparoscopic entrapment sack introduced into the abdomen by the surgical assistant through the 12-mm assistant trocar and stored in the abdomen until completion of the vesicourethral anastomosis.

Bladder Neck Reconstruction

The bladder opening is often slightly larger than the urethral lumen, but a parachuting effect can be achieved during the vesicourethral anastomosis that allows direct approximation of the bladder neck to the urethra. If the bladder neck opening is considerably larger than the urethra, a tennis racquet handle closure can be performed using absorbable suture either posteriorly or anteriorly to allow a better size match with the urethra. In the event of a large prostate gland, median lobe, or prior TURP, the bladder neck often may be disproportionately larger than the urethra and thus may require extensive reconstruction before performing the anastomosis. Often, in these circumstances, the ureteric orifices are located at or near the posterior margin of the bladder neck, where they are at risk for injury or obstruction during suturing of the anastomosis. In such cases the ureteric orifices can be imbricated by placing a few interrupted sutures at the 5- and 7-o'clock positions along the posterior bladder neck using 3-0 polyglactin or polydioxanone suture. This maneuver can help avoid inadvertent sutures passing through or near the ureteric orifices during the anastomosis while at the same time reduce the size of the bladder neck opening. Alternatively, ureteral stents may be placed to protect the integrity of the ureteric orifices during completion of the anastomosis and then removed immediately postoperatively or in a delayed fashion.

Posterior Support of the Vesicourethral Anastomosis

As a result of prostatectomy the posterior supportive layers of the bladder and prostate are divided, including Denonvilliers fascia and its confluence with the posterior rhabdosphincter. Reports of attempts at reconstruction of these posterior supportive structures have suggested improvement in earlier postoperative return of urinary control (Rocco et al, 2007), whereas others have found no significant benefit (Menon et al, 2008). Reconstituting the posterior support to the anastomosis is accomplished by reapproximating the remnant Denonvilliers fascia and posterior bladder neck to the posterior rhabdosphincter beneath the urethra using a running continuous 2-0 poliglecaprone (Monocryl) suture before completion of the vesicourethral anastomosis (Fig. 115-17). Although the exact mechanism remains unclear, suggested mechanisms include reestablishment of the posterior anatomic support to the bladder and urethra, improving urethral coaptation during voiding, reduced tension at the vesicourethral anastomosis, and increase in the functional length of the striated urethral sphincteric complex. Despite the ongoing debate on its effectiveness, many think this step at the very least reduces the distance between the bladder neck and urethra, thus facilitating completion of a tension-free vesicourethral anastomosis. Resuspension of the anastomosis and distal bladder neck to the arcus tendineus is used by some to restore anterior urethral support and preserve the vesicourethral angle (Tewari et al, 2007).

Vesicourethral Anastomosis

With LRP, the vesicourethral anastomosis is one of the most technically challenging aspects of the procedure because of the need for laparoscopic suturing. The da Vinci surgical robot greatly facilitates suturing of the anastomosis due to the ergonomics of the wristed robotic instrumentation. Although interrupted sutures may be used for the anastomosis, van Velthoven and colleagues (2003) described

Figure 115-17. Modified Rocco stitch. Posterior support is provided to the vesicourethral anastomosis by reapproximating the remnant Denonvilliers fascia and posterior detrusor along the posterior bladder neck to the posterior rhabdosphincter using a running continuous 2-0 Monocryl suture. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Figure 115-18. Running vesicourethral anastomosis. The posterior anastomosis is reapproximated after preplacing two or three suture throws on either side starting at the 6 o'clock position and cinching the sutures by lifting anteriorly. Great care must be taken to avoid incorporating the neurovascular bundles (NVBs) when placing sutures within the urethra. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

a running suture technique that distributes tension broadly across multiple points along the bladder neck and urethra. Typically, two separate sutures are tied together at their ends, each 6 to 8 inches in length. The anastomosis between the bladder and urethra begins posteriorly, leaving two needles to run progressively in an anterior direction on either side, finally ending at a single anterior tie. Dedicated mucosal eversion sutures at the bladder neck, commonly used during RRP, are unnecessary with the excellent running mucosa-to-mucosa anastomosis achieved with LRP and RALP. Multiple sutures are first placed through the urethra and bladder before progressive cinching of the anastomosis by lifting each arm of the suture in an anterior direction (Fig. 115-18). Either an assistant or the robotic ProGrasp forceps can be used to grasp one arm of the suture to maintain tension and approximation of the posterior anastomosis while the surgeon reapproximates the contralateral side of the anastomosis using the second suture. The final urethral catheter is passed under direct vision immediately before completion of the anastomosis, and the bladder is irrigated to make certain that there are no leaks. Further sutures may be required if a leak is identified.

Delivery of the Specimens and Exiting the Abdomen

Before undocking the robot and removal of the specimens, the pelvis and operative field should be carefully inspected for bleeding under low insufflation pressure (<10 mm Hg). The bowel should be examined closely to make certain there is no injury resulting from instrument exchanges. The string for the laparoscopic entrapment sack is transferred to the camera port site at the umbilicus and the abdomen is completely desufflated. The specimens within the entrapment sack are extracted intact through extension of the umbilical trocar site. The fascial defect is then closed by open suture placement, and the skin defects are closed with a subcuticular absorbable suture. Closure of the fascial defect for the 5-mm trocar sites is generally not necessary. Because of the potential risk for a trocar site hernia, it is advisable to close the 12-mm trocar sites with a Carter Thomason fascial closure device, especially if a bladed (vs. dilating) trocar is used.

POSTOPERATIVE MANAGEMENT

With the secure and watertight running anastomosis typically achieved, a pelvic drain may not be always necessary. However, a drain may be placed through one of the 8-mm robotic trocar sites and does not require a separate stab wound. The drain may evacuate an unanticipated urine leak or lymphatic fluid collection. Often, though, drainage is minimal and the drain typically can be removed on the first or second postoperative day. Parenteral narcotic medications may be required for the first 24 hours after surgery but should be used sparingly. Instead, ketorolac may be used in selected patients for postoperative pain control.

The duration of time required for the urethral catheter depends to a great extent on the preferred approach of the surgeon, as well as the extent of bladder neck reconstruction. The 2-week period commonly used with open surgery is in general unnecessary if a good running vesicourethral anastomosis is achieved. With 1 week or more of an indwelling urethral catheter, the vast majority of patients are able to void adequately with minimal risk for urinary retention and need for catheter replacement. Performing a cystogram before removal of the catheter is based on surgeon preference. If catheter removal before a week is planned, it may be advisable to obtain a cystogram to ensure there is no extravasation from the anastomotic site. In cases of extravasation, longer duration of the urethral catheter is required to allow for spontaneous healing. Although this may prolong the time to achieve complete urinary continence, long-term urinary outcomes do not appear to be affected (Patil et al, 2009). Some surgeons advocate suprapubic catheter drainage of the bladder with a specially designed anastomotic splint rather than a urethral catheter with good initial results (Tewari et al, 2008).

After LRP and RALP, some degree of postoperative ileus is not uncommon. Most patients can tolerate a regular diet within 24 hours of surgery, and hospitalization beyond the first postoperative day typically is not necessary. Patients can characteristically return to their preoperative activities shortly after catheter removal but must avoid strenuous activity up to 3 to 4 weeks after surgery.

KEY POINTS: TECHNIQUE OF LAPAROSCOPIC AND ROBOTIC-ASSISTED LAPAROSCOPIC RADICAL PROSTATECTOMY

- Use of a transperitoneal or extraperitoneal approach is based primarily on surgeon preference because there is no consistent advantage of one approach over the other.
- The robotic technology facilitates suturing and dissection for surgeons who may not have advanced laparoscopic skills.
- Identification of the precise margin between the bladder neck and prostate can be accomplished by using a set of physical maneuvers and visual cues.
- After division of the anterior bladder neck, the presence or absence of a median lobe should be defined before division of the posterior bladder neck.
- Complete mobilization of the plane between the posterior prostate and rectum is an important step in avoiding rectal injury and defining the medial aspect of the NVBs.
- Use of thermal energy should be minimized during control of the prostatic pedicles and dissection near the NVBs because thermal energy has been shown to be deleterious to cavernous nerve function in both animal and human studies.
- An interfascial dissection of the NVB is preferred in patients with presumed organ-confined cancer who desire NVB preservation for potency.
- An anterior or posterior protruding lip of prostate should be anticipated when dividing the prostatic apex from the urethra so as to avoid an iatrogenic positive apical margin.
- Bladder neck reconstruction may be required if there is a size discrepancy between the bladder neck and urethra, especially in patients with prior TURP, median lobe, or large prostate gland.
- The vesicourethral anastomosis is most efficiently accomplished with a running continuous suture.

Published results continue to emerge with regard to midterm outcomes of LRP and RALP both in the United States and abroad, suggesting comparable outcomes with RRP. Most of these reports, however, are case series. Few randomized trials have been conducted evaluating laparoscopic and robotic versus open techniques, and retrospective comparisons are limited by disparities in surgeon experience, the influence of patient selection, and nonstandardized methods of outcome assessment.

Perioperative Outcomes

Operative Time

The duration of surgery is typically longer with LRP or RALP compared with open surgery, especially early in a surgeon's experience. In fact, operating times are often used as a surrogate for assessing the "learning curve" with minimally invasive prostatectomy (Herrell and Smith, 2005). As both surgeon and operating team experience is gained, virtually all reported series have documented a substantial decrease in operative times that approach and in some series are less than those for open surgery. At experienced centers of excellence with LRP, operative times less than 3 to 4 hours are common (Turk et al, 2001; Salomon et al, 2004; Stolzenburg et al, 2008). Similar findings have been observed with RALP. Inexperience of both the console surgeon and the tableside operating team can lead to lengthy procedures initially. As a result, novice surgeons should pay particular attention to the unique complications that may occur as a result of prolonged pneumoperitoneum in the steep Trendelenburg position, including hypercarbia, acidosis, fluid overload, increased intraocular pressure, and neurapraxias, as discussed earlier in the Preoperative Preparation section of this chapter. Nevertheless once experience is gained, operative times of 3 hours and even less are routine (Smith, 2004; Badani et al, 2007; Patel et al, 2008).

Postoperative Pain

One of the distinct advantages of laparoscopy for many surgical procedures (e.g., laparoscopic nephrectomy) is its minimally invasive nature resulting in less postoperative pain than comparative open approaches. For radical prostatectomy, however, this advantage seems to be less dramatic because RRP is performed through an infraumbilical muscle-splitting incision. In addition, relatively little pain occurs after radical perineal prostatectomy. Some series have shown decreased pain in patients undergoing either LRP or RALP compared with RRP (Menon et al, 2002; Bhayani et al, 2003). Other reports have shown no substantial difference in postoperative narcotic use or patient-reported pain (Webster et al, 2005). **The lack of a significant advantage for laparoscopic prostatectomy from a postoperative pain perspective is attributable primarily to low pain scores even in the open surgical group.**

Intraoperative Blood Loss

Because most of the blood loss that occurs during radical prostatectomy is from venous sinuses, the tamponade effect from the pneumoperitoneum helps diminish ongoing blood loss during LRP and RALP. Further, the antegrade approach used during LRP and RALP allows earlier control of the prostatic pedicles and late division of the deep DVC compared with RRP, in which the DVC is divided early and the arterial supply to the prostate managed late in the operation. Thus the potential for ongoing bleeding is reduced during LRP and RALP as compared with open surgery. Both of these factors, as well as the excellent visualization with laparoscopy, account for the minimal blood loss reported in most laparoscopic and robotic series (Ficarra et al, 2009a).

Perhaps the most meaningful parameter clinically is the proportion of patients requiring transfusion of blood products. Most studies have shown a significant decrease in transfusion requirement for patients undergoing LRP or RALP compared with RRP (Tewari et al, 2003; Ahlering et al, 2004a). Others have shown no statistically significant difference if the transfusion requirement with RRP can be limited to only a few percent of patients (Farnham et al, 2006).

Hospital Stay

Over the past decade, hospital stay after radical prostatectomy has diminished remarkably regardless of the surgical approach. Some centers have reported a length of stay as short as 1 or 2 days after RRP (Holzbeierlein and Smith, 2000). With LRP and RALP, a hospital stay of only 1 day has become routine at many centers. Large population-based studies also have consistently demonstrated that RALP is associated with a shorter length of hospital stay and lower probability of prolong hospitalization (Trinh et al, 2012; Liu et al, 2013; Davis et al, 2014). Ileus and inability to tolerate a regular diet are the most common factors limiting early discharge. Pain control does not typically contribute to prolonged length of stay because long-term parenteral narcotics are rarely required. **With early discharge programs for radical perineal and RRP being commonly used at many centers within the United States, no distinct advantage exists with LRP or RALP, although discharge on the first postoperative day may be more easily accomplished routinely with the minimally invasive approaches.**

Functional Outcomes

The complications of radical prostatectomy with the greatest potential for an adverse effect on quality of life are urinary incontinence and erectile dysfunction. Greater surgical experience with radical prostatectomy and refinements in surgical technique have reduced the frequency with which these problems are observed in most radical prostatectomy series from centers of excellence. However, most large population-based studies show substantial rates of erectile dysfunction and incontinence after both RRP and radical perineal prostatectomy (Fowler et al, 1993). Whether laparoscopic or

robotic approaches offer improved functional outcomes is still a matter of debate, and comparison of published series is difficult because of differences in patient populations and methods of outcome assessment.

Urinary Incontinence. Urinary incontinence after radical prostatectomy is usually manifested as stress incontinence secondary to intrinsic sphincter deficiency. Although more than 90% of patients ultimately regain good urinary control and do not require pads for incontinence in reports from high-volume centers (Walsh, 1998; Catalona et al, 1999), other studies have shown that a substantial proportion of patients may be bothered by some degree of stress incontinence (Fowler et al, 1993). The exact physiologic mechanisms that contribute to urinary control after radical prostatectomy are not entirely understood and are likely multifactorial. However, surgical technique is undoubtedly a contributing factor (Smith, 2002).

With LRP and RALP, visualization of the prostatic apex is typically superb. The minimal bleeding and magnification of the operative field allow precise dissection of the prostatic apex with limited trauma to the periurethral striated sphincter and genitourinary diaphragm. As mentioned previously, the ability to more reliably accomplish a tension-free, watertight anastomosis under the superior and direct visualization offered by laparoscopic approaches in theory favors LRP and RALP over open surgery. A common observation after radical prostatectomy, regardless of surgical approach, is that urinary incontinence improves substantially within the first 3 to 6 months after surgery and to some extent for another year or more. Therefore the time points at which data on incontinence are collected are highly influential. Differences exist whether the information is gathered by questionnaire, the physician, or an independent third party. Further, even though validated instruments for assessment of incontinence exist, the manner and location in which the data are collected can affect results. Although the method used to evaluate continence in reported series varies, the recovery of urinary continence is in general excellent at 1 year after LRP and RALP with comparable and in some cases superior results compared to RRP in published comparative studies (Table 115-1). More recent reports of techniques that provide both posterior and anterior support to the vesicourethral anastomosis report even further improvements in urinary continence, especially at earlier time points (Tewari et al, 2007; Johnson et al, 2011).

Erectile Dysfunction. Preservation of erectile function after radical prostatectomy depends on precise and meticulous separation of the cavernous nerves within the NVB from the prostate gland (Walsh and Donker, 1982). The anatomic course of these nerves has been described but can be variable (Costello et al, 2004; Takenaka et al, 2004; Lunacek et al, 2005). Intraoperative localization using nerve stimulation has not been sufficiently accurate for clinical utility (Holzbeierlein et al, 2001). The principles and anatomic dissection for nerve preservation are the same regardless of surgical approach. It is still uncertain whether the magnified image of the operative field afforded by laparoscopy and the precision of the surgical instruments allow more anatomically accurate and less traumatic dissection of the NVBs, resulting in improved postoperative erectile function. As with incontinence, comparison of the published literature is difficult (Salomon et al, 2004). Differences in the method of assessment, definition of potency (e.g., spontaneous erections vs. intercourse), and patient selection complicate comparisons. In addition, the use of adjunctive therapies such as phosphodiesterase-5 inhibitors or vasoactive injections can substantially influence results. Also, in concordance with other nerve injuries, improvement in erectile function is a prolonged process that is ongoing for years after radical prostatectomy. **Results from published comparative series suggest that RALP may provide equivalent, or in some cases slightly better, erectile recovery compared to that with RRP when performed by experienced surgeons (see Table 115-1).** Furthermore, RALP potency outcomes appear superior to that of LRP at least in some single-surgeon observational series (Park et al, 2011; Willis et al, 2012). Thompson and colleagues (2014) reported higher sexual function scores after transition to RALP compared to RRP when performed by an experienced surgeon. Although this and

other published series report relative improvement in recovery of sexual function after RALP and LRP, patient-reported outcomes indicate that erectile dysfunction remains a major limitation even in modern surgical series. Sanda and colleagues (2008) demonstrated significant decline in patient-reported sexual scores and quality of life with infrequent complete recovery to baseline function even despite nerve-sparing surgery among men treated with both RALP and RRP. Nevertheless, most surgeons would agree that with regard to surgical technique, avoidance of traction, direct manipulation, hemostatic energy sources, and performance of a meticulous interfascial dissection during NVB preservation appear to be critical to optimizing postoperative recovery of potency.

Anatomic studies indicate that the cavernous nerves in the NVB course posterolateral to the prostate and urethra. A technique during RALP for preservation of more anteromedial periprostatic fascia in addition to the conventional NVB regions has been reported to significantly improve potency outcomes (Menon et al, 2005; Saveria et al, 2006). Although some neural tissue can be shown histologically to travel within the anterior and medial periprostatic fascia, the purpose and significance of these nerves and their relative contribution to erectile function remains uncertain. Nevertheless, the concept of optimizing both qualitative and quantitative preservation of nerve fibers traveling within the periprostatic fascial planes irrespective of whether they affect penile erections or urinary continence seems reasonable. In cases in which wider excision of the nerve bundles is required, incremental nerve preservation is often feasible without having to excise the entire NVB. Finally, cavernous nerve grafting and nerve advancement have been described; however, the true merits of these techniques remain unclear (Martinez-Salamanca et al, 2007; Zorn et al, 2008).

Oncologic Outcomes

Surgical margin status and biochemical recurrence have generally been used as surrogates for oncologic efficacy after radical prostatectomy.

Surgical Margins. The goal of radical prostatectomy is complete surgical removal of the entire prostate and its investing fascia, as well as the seminal vesicles. Because most adenocarcinomas of the prostate occur in the peripheral zone and approach the capsular margin, surgical technique can influence oncologic outcomes. Proper surgical dissection should allow negative margins with pathologic stage T2 tumors while also permitting complete excision and negative margins for some extracapsular lesions. Efforts to avoid urinary incontinence or erectile dysfunction by dissecting too closely to the prostatic apex or the posterolateral aspect of the prostate can compromise margins, regardless of the surgical approach. **Importantly, the method and detail of pathologic analysis of the surgical specimen can be highly influential in assessing surgical margin status.** Some reports have used only biopsies of remaining tissue after removal of the surgical specimen to assess margin status, whereas others rely on step-sectioned routine or whole-mount histology. According to the World Health Organization International Consultation Consensus Committee guidelines established for the pathologic analysis of prostatectomy specimens, whole-mount histologic sectioning may miss areas of extraprostatic extension in 7% to 15% of cases and positive margins in up to 12% compared with specimens analyzed by routine sectioning (World Health Organization International Consultation on Prediction of Patient Outcome in Prostate Cancer, 2004). This finding is thought to be due to the relatively thicker slices required during sectioning of the prostate for whole-mount technique compared with the serial 3- to 5-mm slices used during routine sectioning.

In most series of LRP and RALP, positive margin percentages decrease with experience (Ahlering et al, 2004b; Salomon et al, 2004; Rassweiler et al, 2005). This implies that inexperience with the surgery accounts for positive margins in some cases. Sometimes, this may be from difficulty in identifying the proper anatomic plane of dissection between the bladder neck and the base of the prostate. **The most common site of a positive margin, whether**

the operation is performed via open or laparoscopic approaches, is the prostatic apex (Touijer et al, 2005). Insufficient removal of prostatic tissue at the apex in an effort to optimize urethral length and avoid incontinence can result in positive margins even with tumors that do not pathologically violate the capsule (i.e., stage pT2). As mentioned previously in the discussion of surgical techniques in this chapter, adhering to specific surgical principles can help reduce site-specific positive margins at the apex, bladder neck, and posterolateral regions of the prostate. Low positive margin rates have been reported by experienced centers with LRP and RALP reporting pT2-positive margins between 4% and 10% and pT3-positive margins between 21% and 35% (Guillonneau et al, 2003a; Lein et al, 2006; Badani et al, 2007; Smith et al, 2007; Patel et al, 2008; Stolzenburg et al, 2008). Results from published com-

parative studies of pathologic stage-specific positive margins among RRP, RALP, and LRP are shown in Table 115-2.

The primary factor that determines the positive margin rate in a given series is patient selection. As discussed earlier, the method and detail of pathologic analysis is also influential. Evaluating positive margin rates from one series to another, then, is not necessarily a comparison of surgical technique. A more accurate technical comparison is analysis of the pathologic results in stage T2 tumors in which a positive margin implies surgical violation of the prostatic capsule. Even in this circumstance, though, the methodology for pathologic sampling is important. Intrainstitutional comparisons from some studies have shown a reduced rate of positive margins with laparoscopic approaches compared with RRP. However, comparison of margin status between high-volume

centers with operations performed by experienced surgeons has shown no consistent advantage for one surgical approach over the other in achieving negative surgical margins (Brown et al, 2003; Khan et al, 2005).

Biochemical Recurrence. Biochemical recurrence after prostatectomy perhaps may provide a more accurate assessment of oncologic control than margin status. Guillonnet and colleagues (2003a) reported on their oncologic outcomes with 1000 consecutive LRPs performed over a 4-year period with a median follow-up period of 12 months. Their overall actuarial biochemical progression-free survival rate was 90.5% at 3 years. By pathologic stage, the rates were 92% for pT2a, 88% for pT2b, 77% for pT3a, and 44% for pT3b. Pavlovich and colleagues (2008) reported on 528 consecutive LRP patients with a mean follow-up of 13 months. The 3-year, actuarial, biochemical-free survival was 94.5% overall, 98.2% for pT2, and 78.7% for pT3 disease.

With regard to RALP, Badani and colleagues in 2007 reported on their large series of 2766 consecutive RALP patients with a mean follow-up period of 22 months. Their overall 5-year, actuarial, biochemical-free survival was 84% overall, 84% for pT2, and 66% for pT3 patients. It should be noted that their patient population included patients at higher risk than those in most reported series with a Gleason score of 7 or higher in 64% and a pathologic stage of pT3 or higher in 22% of their patients. A growing number of

studies have reported oncologic outcomes after RALP similar to those seen with open prostatectomy. In particular, stage- and risk-stratified positive surgical margin and biochemical-free recurrence rates appear to be comparable between RALP and RRP once the learning curve for robotic prostatectomy has been surpassed (see Table 115-2) (Schroek et al, 2008; Silberstein et al, 2013). In one large study comparing 277 RRP and 730 RALP cases, Park and associates (2014) reported no significant difference in T2-positive surgical margin rates between the two approaches, and similar 3-year biochemical-free recurrence survival for both T2 (92.1% vs. 96.8%, $P = .52$) and T3 cases (60.0% vs. 67.3%, $P = .27$). Other studies have reported similar results, even in high-risk disease (Masterson et al, 2013; Punnen et al, 2013; Vora et al, 2013). Taken together, the information available to date indicates that RALP and RRP offer similar disease control when performed by experienced surgeons, even in high-risk settings.

Randomized Comparisons of Open versus Minimally Invasive Prostatectomy

Although a number of studies have reported surgeon and institutional outcomes associated with robotic prostatectomy, direct comparisons of robotic prostatectomy to open radical prostatectomy

are remarkably scant. The vast majority of comparative evidence has been gained through observational studies and case series thus far, although efforts to better study robotic and open prostatectomy are currently underway through a randomized controlled trial (Gardiner et al, 2012). This trial will report oncologic efficacy through positive margin rates, biochemical failure rates, and subsequent salvage treatment-free rates, as well as other noncancer outcomes, such as complications and recovery of urinary and sexual function. Three trials comparing open prostatectomy to minimally invasive prostatectomy have been completed thus far. One study comparing laparoscopic prostatectomy to open prostatectomy confirmed that laparoscopic prostatectomy was associated with less blood loss and lower transfusion rates than open surgery (Guazzoni et al, 2005). Two other randomized controlled trials comparing laparoscopic prostatectomy to RALP did not demonstrate differences in perioperative outcomes, although RALP was associated with better postoperative erectile function and recovery of urinary continence than laparoscopic prostatectomy, perhaps reflecting the technical difficulty and steep learning curve associated with laparoscopic prostatectomy (Asimakopoulos et al, 2011; Porpiglia et al, 2013).

Economic Considerations

Both the duration of surgery and equipment expenses contribute to operating room costs for LRP and RALP, which typically are higher than those for open approaches (Link et al, 2004; Lotan et al, 2004; Scales et al, 2005). This is particularly true with robotic-assisted surgery. Current purchase cost of a da Vinci S system is approximately \$1.65 million, with an average cost of \$2400 for each multiple-use (10 lives) robotic instrument. For robotic instrumentation, this would translate to approximately \$1200 per case for the use of five separate robotic instruments with an additional \$325 per case for disposables (sterile robotic drapes and trocar seals).

In the study by Link and colleagues (2004), the factors that most influenced overall LRP cost in order of importance included operative time, length of hospital stay, and consumable items (e.g., disposable laparoscopic equipment and trocars). They found that the calculated cost equivalence between RRP and LRP could be met if disposable equipment was eliminated by using reusable items and operative times for LRP were reduced to 3.4 hours. Lotan and colleagues (2004) found that RALP costs were approximately \$1155 per case more than RRP if the initial purchase cost of the robot were excluded. A more recent systematic review reported that minimally invasive prostatectomy (RALP and LRP) was more costly than RRP in most studies reviewed, largely secondary to higher direct costs. For example, reported costs for minimally invasive radical prostatectomy ranged from \$5058 to \$11,806, compared to \$4075 to \$6296 for RRP (Bolenz et al, 2014). Another single-institutional study reported significantly higher operating room costs for RALP compared to RRP, and an average payment to cost differential of \$1325 for RRP and -\$4013 for RALP, indicating per case loss associated with minimally invasive prostatectomy (Tomaszewski et al, 2012). In a local cost analysis performed by Scales and colleagues (2005), they found that RALP would be less expensive than RRP in some practice settings in which RALP hospital stay was less than 1.5 days if case volumes increased to 14 cases per week. Others also have found this same inverse relationship of case volume to cost drawing from the United Kingdom National Health Service data (Close et al, 2013). These studies suggest that RALP may be more economically viable in high-volume centers.

These increased costs may be partially mitigated by shorter hospital stays compared with open surgery. The decrease in expense for hospital stay depends partly on the discharge day for the laparoscopic procedure but also the customary length of stay at a given hospital for open radical prostatectomy. Published reports detailing a length of stay of a week or more for RRP are not in concordance with other contemporary reports in which patients are discharged on the second or even first postoperative day after radical perineal or RRP (Holzbeierlein and Smith, 2000).

COMPLICATIONS

Complications Related to Patient Positioning

It is important to note that specific lower extremity neuropathies have been reported that are unique to this steep Trendelenburg positioning, especially after prolonged surgeries (Koc et al, 2012). The frequency of these lower extremity neuropathies appears to be low (1.3%) and transient. Of note, femoral nerve compromise has been described as a result of excessive hyperextension of the hip to allow for proper docking of the fourth robotic arm. This may result in compression of the femoral nerve as it courses beneath the inguinal ligament with resultant transient motor and sensory neuropathy. To minimize this complication, hyperextension at the hip should be minimized to only what is necessary for docking of the robotic arms and operative time should be kept to a minimum. Pneumoperitoneum in the steep Trendelenburg position also has been associated with a transient increase in intraocular pressure with decline to baseline pressures on returning the patient to the supine position (Awad et al, 2009). Among other potential causes, two operative variables appear to contribute significantly to this observation: including operative time (and hence higher central and orbital venous pressure) and end-tidal CO₂ level (with resultant increase in arterial CO₂ leading to choroidal vasodilation). Although the clinical effect of this transient phenomenon is unclear and generally unapparent in healthy individuals, it may pose particular concern in some elderly patients who have elevated intraocular pressures at baseline (e.g., glaucoma). It is unknown whether this effect is causally associated with the rare reports of acute visual loss after minimally invasive prostatectomy as a result of posterior ischemic optic neuropathy (Weber et al, 2007). Nevertheless, it is advisable that both surgeon and anesthesiologist inquire about preexisting ocular disease in the preoperative screening of patients who select to undergo minimally invasive prostatectomy.

Vascular and Bowel Injury

Vascular or bowel perforations are rare but can occur during placement of abdominal trocars. In addition, once safe trocar placement is established and the robot is docked, care must be taken to avoid injury along the path of the multiple instruments, which must be interchanged and directed toward the pelvis. The key to managing such major postoperative complications is prompt recognition and immediate repair of injury to bowel or blood vessels. Often, relatively minor injuries can be repaired laparoscopically, although there should be no hesitation to convert to an open approach in the face of a more complex injury.

Open Conversion

Open conversion is rare (<2%) and has been cited in the literature, usually during a surgeon's early experience with LRP or RALP, mainly as a result of failure to progress or uncertainty of dissection planes (Bhayani et al, 2004). With experience, the need for open conversion is rare; however, patients must be properly counseled on this possibility.

Rectal Injury

Rectal injuries, although uncommon during LRP and RALP (0.7% to 2.4%), have been reported and repaired successfully by laparoscopic means (Guillonneau et al, 2003b; Katz et al, 2003; Gonzalgo et al, 2005). Intraoperative recognition and repair of the injury is crucial. Multilayered primary closure with or without interposition of omentum between the rectum and anastomosis usually can avoid long-term problems, as well as the need for open conversion and intestinal diversion. Inadequate closure or lack of recognition can result in a rectourethral fistula. If a small rectal injury is suspected but not readily visible, insufflation of air into the rectum using a catheter inserted into the rectum with fluid within the pelvis

(i.e., air bubble test) often can demonstrate small bubbles at the site of the injury.

Thromboembolic Complications

The 2008 AUA Best Practices Statement recommends the routine use of intermittent pneumatic compression devices for laparoscopic and robotic urologic procedures. However, it does not recommend routine use of prophylactic anticoagulants for these procedures unless a patient has multiple known risk factors such as obesity, advanced age, malignancy, immobility, or a history of deep venous thrombosis (DVT). Nonetheless, because of the known venous stasis and hypercoagulable state that can occur during pelvic surgery in patients with known malignancy, these patients are still at risk (albeit low) for thromboembolic problems. The incidence of thromboembolic complications after LRP and RALP has been reported to be as low as 0.5%, in part as a result of faster postoperative patient mobilization and Trendelenburg positioning, which decrease venous stasis in the lower extremities compared to open surgery (Secin et al, 2008). The presentation of DVT in the lower extremities should prompt immediate anticoagulation and consideration for obtaining a pelvic computed tomography (CT) scan or ultrasonography to exclude a lymphocele, hematoma, or urinoma that could be compressing the external iliac vein, thus increasing the risk for a DVT.

Anastomotic Complications

Failure to achieve a watertight closure of the anastomosis can result in urinary extravasation and accumulation of urine even if a pelvic drain is placed. This is even more problematic with a transperitoneal approach because the entire abdominal cavity becomes accessible for urine egress. In such cases a cystogram should be performed to make certain there is some degree of integrity of the anastomosis. Fluid accumulation may require percutaneous drainage. Most small anastomotic leaks will resolve spontaneously with prolonged urethral catheter drainage. If complete disruption of the anastomosis has occurred, surgical revision—laparoscopic, robotic, or open—is indicated if the problem is recognized in the first few days after surgery.

Anastomotic stricture resulting in bladder neck contracture seemingly occurs at a lower rate after LRP and RALP compared with open surgical approaches, especially in the hands of experienced surgeons. Rates of less than 2% have been reported (Msezane et al, 2008; Webb et al, 2009). This implies that achievement of a watertight anastomosis with good mucosal approximation is the key measure in preventing postoperative bladder neck contracture.

Bleeding and Transfusion

Virtually all published reports have documented a distinct advantage for laparoscopic surgery in diminishing the amount of bleeding that occurs with radical prostatectomy. Transfusion requirements of 2% or less are commonly reported (Ficarra et al, 2009a). The tamponade effect of the pneumoperitoneum compresses venous bleeding, and the superb visualization allows prospective identification of bleeding vessels that require hemostasis. However, in addition to the risk for major vascular injury from the surgical dissection or trocar placement, there is the possibility of postoperative bleeding once the pneumoperitoneum is relieved. As mentioned previously, the pelvis and surgical field should be carefully inspected for the presence of bleeding at the end of the operation under low insufflation pressure. Because of the low incidence of postoperative bleeding, though, routine use of topical hemostatic agents along the prostate bed is not generally required.

Equipment Malfunction

The surgeon is highly dependent on sophisticated technology and equipment for performance of LRP and, in particular, RALP. Equipment malfunction, especially with RALP, can create problems that

make it difficult to progress with surgery and may result in case cancellation or conversion to pure laparoscopic or even open surgery. Zorn and colleagues (2007) identified recoverable errors in 0.4% of RALP cases performed at their institution. Lavery and colleagues (2008) found a 0.4% nonrecoverable malfunction rate in their multi-institutional study of high-volume RALP centers. Although the possibility of conversion to a pure laparoscopic or open surgical approach in the event of an unrecoverable equipment malfunction is extremely rare, patients need to be properly counseled in regard to this.

KEY POINTS: RESULTS AND COMPLICATIONS OF LAPAROSCOPIC AND ROBOTIC-ASSISTED LAPAROSCOPIC RADICAL PROSTATECTOMY

- Blood loss and transfusion rates are generally lower with LRP and RALP compared with open surgery and is in part attributed to improved visualization with anticipation of bleeding and the tamponade effect of pneumoperitoneum.
- Operative times are initially longer with minimally invasive approaches compared to open surgery but comparable once experience is gained.
- Excellent postoperative urinary continence is routinely achieved after LRP and RALP owing to the minimal bleeding and magnification of the operative field, allowing precise dissection of the prostatic apex with limited trauma to the periurethral striated sphincter in addition to the ability to reliably accomplish a tension-free, watertight anastomosis.
- Published comparative studies suggest comparable and in some cases superior potency outcomes with RALP compared to RRP in experienced hands.
- Stage- and risk-stratified positive surgical margin and early biochemical-free recurrence rates appear to be comparable among LRP, RALP, and RRP at experienced centers.
- Higher costs are still a concern, especially with the robotic-assisted approach, but may be partially offset but shorter hospital stays and higher case volumes.
- Increased intraocular pressure and rare cases of femoral neurapraxia have been reported, especially in prolonged cases with patients in the steep Trendelenburg position.
- Thromboembolic events, open conversion rectal injury, transfusion, and equipment malfunction are rare events with both LRP and RALP.

ROBOTIC SALVAGE PROSTATECTOMY

Biopsy-proved persistence or recurrence of cancer within the prostate after definitive nonsurgical treatments is a particularly challenging situation. Salvage surgery can be beneficial in selected patients but is associated with a significantly higher complication rate than with patients not previously treated. In particular, the incidence of urinary incontinence, erectile dysfunction, bladder neck contracture or anastomotic leak, and rectal injury is higher with salvage surgery. Nonetheless, surgical removal of the prostate offers a potentially curative option after failure of prior therapy and may have application in selected patients previously treated with radiation whether by external-beam, brachytherapy, or proton beam. In addition, patients treated with cryotherapy or high-intensity focused ultrasonography may be eligible for robotic salvage prostatectomy. Historically, salvage prostatectomy was performed relatively infrequently secondary to the technical challenges and the desmoplastic reaction caused by prior treatments. An additional concern was the relatively high reported rate of rectal injuries of more than 15% in some open salvage prostatectomy series (Chen and Wood, 2003). Despite this, in experienced hands robotic salvage prostatectomy has been shown to be feasible and safe in several reported series, with early outcomes comparable to those with open surgery (Kaouk et al, 2008; Boris et al, 2009; Chauhan et al, 2011; Kaffenberger et al, 2013; Yuh et al, 2014).

Patients most suitable for robotic salvage prostatectomy are those with biopsy-proved persistent cancer but with no evidence of disease outside the prostate. Considering the potential morbidity of the operation, proper selection of patients who may benefit from surgery is paramount. **Ideally, PSA should be less than 10 ng/mL because values above that level, especially in a previously treated patient, may indicate a high likelihood of extraprostatic disease.** A CT scan and bone scan should be obtained to assess for distant disease even in patients with relatively low PSA when considering salvage prostatectomy. In addition, patients should have a life expectancy of 10 years or more to derive benefit from surgery. Preoperative preparation is similar to that in patients undergoing standard RALP. Of note, a bowel preparation with magnesium citrate and Fleet enema the day before surgery is advisable given a potential higher risk for rectal injury.

Surgical Technique

Development of the extraperitoneal space along the pelvic sidewall, as well as the space of Retzius, can be more difficult in patients previously treated with external-beam irradiation. Caution must be used in dissecting the bladder from the iliac vessels because of the desmoplastic reaction that is often encountered. These tissue planes typically are preserved in patients who received brachytherapy, cryotherapy, or high-intensity focused ultrasonography.

Incision of the endopelvic fascia is performed to help identify the contour of the prostate. Suture control of the deep DVC may be best avoided as an initial step because clear identification of the prostatic apex can be difficult at this point and only minimal back-bleeding occurs. The bladder neck is identified primarily by exposing the lateral margins of the prostate and performing a pinch maneuver with the robotic instruments to demonstrate the prostate–bladder neck junction. The bladder neck may be pale and thickened. Administration of indigo carmine can help identify the ureteric orifices along the bladder trigone, which may be obscured by the fibrosis. Complete dissection of the seminal vesicles should be performed, because the incidence of invasion may be higher in patients with recurrent prostate cancer.

Even though typically there is fibrosis surrounding the entire prostate in a salvage setting, the posterior dissection can be the most difficult because of periprostatic inflammation and scarring as a result of prior treatment effect and the concern of rectal injury. The plane posterior to Denovilliers fascia, however, is typically well preserved, especially near the bladder neck. This facilitates dissection in the perirectal fat plane along the anterior rectal wall to minimize the risk for rectal injury but also to provide good mobilization of the posterior prostate and identification of the prostatic pedicle. A distinct advantage of a laparoscopic (vs. open) approach to salvage prostatectomy is the ability to perform antegrade release of the rectum from the posterior prostate under direct and magnified vision. Dissection in this plane should be performed using primarily sharp dissection with scissors. Blunt separation of tissues should use only minimal tension, and cautery is neither necessary nor advisable. Especially toward the prostatic apex, the dissection becomes even more crucial. This is the area of closest proximity between the rectal wall and the prostate and often the one with the most fibrosis. Despite this, using an antegrade approach, the tissues usually are well visualized so that the dissection can be performed sharply and safely. Often, the titanium capsules used with brachytherapy seeds are encountered during this portion of the dissection.

The deep DVC and the prostatic apex are better identified after the prostate has been mobilized. If the adhesions around the DVC are dense, it is preferable to simply incise the tissue sharply and place a hemostatic suture as required. The prostatourethral margin then should be readily identified and incised. Completion of the anastomosis is performed in the same manner as with a patient not previously treated, but the periurethral tissues may be quite pale and fibrotic. It becomes even more imperative to have a watertight mucosa-to-mucosa approximation.

Complications and Postoperative Care

The rectum should be carefully inspected after specimen removal. **An air bubble test can be performed to localize a small rectal injury that is suspected but is not visibly apparent.** A rectal injury can be repaired primarily, but it is essential that the repair be secure. Omentum may be mobilized to interpose between the bladder and rectum. If the quality of the repair is in doubt, a diverting colostomy should be performed.

The Foley catheter should be left indwelling for at least 2 weeks because of delayed healing with previously treated tissue. A cystogram may be useful to ensure complete anastomotic healing before catheter removal. Bladder neck contracture occurs less frequently than with open salvage prostatectomy but still may be observed and may manifest within a few weeks of catheter removal.

Incontinence occurs at a higher rate in the salvage setting even though most patients do regain complete or at least adequate urinary control. A nerve-sparing procedure to preserve erectile function, although feasible, is often technically difficult owing to the desmoplastic reaction along the periphery of the prostate. **Keeping in mind that the primary intent of salvage prostatectomy is curative, any attempt at preservation of the cavernous nerves should be approached with caution because of difficulty in assessing accurately the local tumor extent beyond the prostate.** Furthermore, the patients suitable for salvage prostatectomy are more likely to already have preexisting erectile dysfunction because of their prior treatment.

KEY POINTS: ROBOTIC SALVAGE PROSTATECTOMY TECHNIQUE AND COMPLICATIONS

- Robotic salvage prostatectomy is associated with a significantly higher complication rate than with patients not treated previously.
- Robotic salvage prostatectomy can be safely performed in selected patients who fail previous treatment, including prior external-beam radiotherapy, brachytherapy, cryotherapy, and high-intensity focused ultrasonography.
- Patients considering salvage prostatectomy ideally should have a PSA less than 10 ng/mL.
- A CT and bone scan should be obtained, and patients should have a life expectancy of 10 years or more, to derive benefit from salvage prostatectomy.
- A distinct advantage of a laparoscopic approach to salvage prostatectomy is the ability to perform antegrade release of the rectum from the posterior prostate under direct and magnified vision.
- Because of difficulty in accurately assessing the local tumor extent beyond the prostate, attempt at cavernous nerve preservation during robotic salvage prostatectomy should be approached with caution keeping in mind that the primary intent is cancer control.
- An air bubble test can be performed to localize a small rectal injury that is suspected but is not visibly apparent.

LAPAROSCOPIC PELVIC LYMPH NODE DISSECTION

Indications

Currently, PLND is rarely indicated as an independent staging procedure. In some patients with a significant risk for nodal metastasis, such as those with a high Gleason grade tumor, a large tumor volume, or a markedly elevated PSA level, PLND may be useful for staging and selection of therapy before external-beam irradiation. Also, staging PLND may have a role in some patients in whom radical perineal prostatectomy is planned. With RRP, LRP, or RALP, it is the usual practice that PLND be performed simultaneously with the radical prostatectomy.

Figure 115-19. Laparoscopic pelvic lymph node dissection. Initial transperitoneal view of the obturator fossa and relevant anatomy. The dashed line indicates the longitudinal incision that is made in the peritoneum lateral and parallel to the median umbilical ligament back toward the bifurcation of the iliac vessels in efforts to provide exposure to the obturator fossa and lymph nodes. Ext., exterior; Int., interior. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Expert opinion about the role of PLND in patients undergoing surgery for carcinoma of the prostate is evolving. Current debate centers around the anatomic boundaries for the procedure, the merits of an extended lymph node dissection, and whether there is any meaningful clinical (i.e., therapeutic) benefit to surgical removal of involved nodes. Most studies show histologic evidence of nodal metastasis in less than 5% of patients with low-risk features in the primary tumor. Consequently, PLND may not be required in patients with clinically localized prostate cancer with PSA less than 10 ng/mL and Gleason score of 6 or less based on the AUA 2013 Revised Best Practice Statement.

PLND is generally recommended in patients with intermediate- or high-risk parameters of the primary tumor, generally implying a PSA of greater than 10, a large palpable nodule, or a Gleason sum of 7 or greater. Historically, a limited or “standard” node dissection has been used by many surgeons. Most contemporary thought and evidence supports an extended node dissection in cases in which node dissection is indicated. The rationale for this approach is a significantly higher yield of nodal tissue and identification of nodal metastasis with extended versus a standard dissection.

Surgical Technique

In laparoscopic staging PLND, trocar configuration is similar to that for LRP and RALP but only one assistant trocar is generally necessary. Abdominal access is established, and an incision is made just lateral to the medial umbilical ligament back toward its confluence with the hypogastric artery and down to the pubis (Fig. 115-19). Great care must be taken to avoid injury to the nearby ureter. If PLND is performed during LRP or RALP, the dissection is simplified because previous mobilization of the bladder provides excellent exposure of the obturator space.

As with an open approach, a key initial step to standard laparoscopic PLND is separation of the nodal packet from the external iliac vein. The lymph node packet is grasped and retracted medially. A relatively avascular plane between the lymph node packet and lateral pelvic sidewall is identified and can be dissected bluntly. Dissection is carried out proximally to the iliac bifurcation and distally to the pubis, thus defining the lateral extent of the lymph

Figure 115-20. Initial dissection of a standard pelvic lymph node template. The vas deferens has been clipped and divided. With medial traction on the lymph node packet, the lateral extent of the dissection is defined using mainly blunt dissection. Ext., exterior. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

Figure 115-21. Final dissection of a standard pelvic lymph node template. The proximal and distal extent of the lymph node packet are clipped and divided, taking great care to avoid injury to the obturator nerve and vessels, as well as the accessory obturator vein. (Copyright Li-Ming Su, MD, University of Florida, 2009.)

node packet. By retracting the lymph node packet medially, the precise course of the obturator nerve and vessels can be identified and protected (Fig. 115-20). After securing the distal extent of the lymph nodes with hemoclips, the packet is divided, retracted cranially, and bluntly separated from the obturator vessels and nerve by blunt dissection. Hemoclips are again placed on the proximal extent of the lymph node packet (Fig. 115-21). The lymph nodes

usually can be removed as a single packet and extracted either through the 12-mm trocar or by placing them in the entrapment sack along with the prostate specimen.

Some controversy remains about the precise anatomic boundaries of an extended node dissection for patients with prostate cancer. Commonly, though, the boundaries are 2 cm cephalad to the bifurcation of the common iliac artery at the point where the ureter crosses over the vessels and distally to the node of Cloquet. The lateral margin should be the genitofemoral nerve, and the medial border is the bladder wall. Complete removal of all nodal tissue surrounding the obturator nerve is essential, and the bladder pedicle should be skeletonized. Presacral nodes often are included with an extended dissection. Extended lymph node dissection can be performed laparoscopically and robotically. The da Vinci Si system allows more proximal angulation of the instruments, and this can significantly facilitate dissection around the bifurcation of the common iliac artery. A thorough dissection adds time to the surgical procedure, but this is true regardless of whether laparoscopic, robotic, or open surgery is performed.

No valid comparative studies exist to support the superiority of open versus laparoscopic PLND. Using lymph node count as a surrogate for adequacy of the dissection is problematic because the method and thoroughness of pathologic evaluation is perhaps even more influential than the anatomic extent of the surgical dissection. With careful attention to meticulous dissection, though, all of the fibrous, fatty, and lymphatic tissue within the commonly accepted anatomic boundaries for an extended lymph node dissection can be removed laparoscopically or robotically. Use of clips on identifiable lymphatic channels can minimize the occurrence of a postoperative lymphocele.

Complications

Because, by definition, PLND requires skeletonization of portions of the common iliac, external iliac, and hypogastric arteries and veins, the possibility of major vascular injury exists. A small venotomy or arteriotomy can be closed laparoscopically with a fine polypropylene (Prolene) suture. A major injury may require rapid conversion to an open approach. However, the incidence of major vascular injury resulting in enough bleeding to require transfusion is well under 1% with PLND.

Transection of the obturator nerve may occur. Direct repair with suturing of the ends of the obturator nerve can restore partial function. Ureteral injury is uncommon, but caution must be observed during the proximal portion of the dissection as the ureter crosses the anterior portion of the common iliac artery.

A transperitoneal approach is not protective against the formation of a lymphocele. Theoretically, the communication with the entire peritoneum would allow distribution and absorption of any lymphatic fluid throughout the peritoneal lining of the abdomen and decrease the risk for lymphocele. Despite this, however, a loculation of lymphatic fluid can occur. Asymptomatic lymphoceles do not necessarily require drainage or treatment. A larger collection can compress the bladder and cause new-onset or worsening irritative voiding symptoms. Compression of the external iliac vein can predispose a patient to DVT in the lower extremity. Secondary infection of lymphoceles also may occur. In the presence of symptoms or complications from a lymphocele, temporary placement of a percutaneous drain is typically successful. However, lymphatic fluid can reaccumulate, requiring repeat drainage with injection of a sclerosing agent or surgical opening of a window with marsupialization of the lymphocele wall by laparoscopic means.

SUMMARY

Over the past decade, LRP and RALP have become accepted surgical approaches for the management of patients with localized carcinoma of the prostate both in the United States and abroad. As expertise with these procedures is achieved, operative times

KEY POINTS: LAPAROSCOPIC PELVIC LYMPH NODE DISSECTION AND COMPLICATIONS

- PLND is generally recommended in patients with intermediate- or high-risk parameters of the primary tumor, generally implying a PSA of greater than 10, a large palpable nodule, or a Gleason sum 7 or higher.
- Although an extended PLND may yield a higher lymph node count, debate continues as to the extent of PLND and the clinical benefit of removing cancerous nodes.
- Use of clips on identifiable lymphatic channels can minimize the occurrence of postoperative lymphoceles.
- A transperitoneal approach is not protective against the formation of a lymphocele because loculation of lymphatic fluid can still occur within the peritoneal cavity.
- Symptomatic lymphoceles, which cause local problems such as venous or bladder compression, may require percutaneous or laparoscopic drainage.

diminish, with times similar to that for RRP. The robotic-assisted technique provides ergonomic advantages for the surgeon and facilitates suturing and other technical aspects of the operation for surgeons who do not have highly advanced laparoscopic skills.

Comparison of outcomes between reported series is imprecise because of differences in patient selection, methods of collecting and reporting data, and the technique of pathologic sectioning and analysis. However, intraoperative blood loss with LRP and RALP has been consistently reported as minimal and transfusion is required in only a small percentage of patients. Postoperative morbidity and return to activity are both improved compared with open surgery in most reports. Good results with postoperative urinary continence and erectile function are reported with mature LRP and RALP series and appear comparable and in some cases superior to RRP when performed by experienced surgeons. Pathologic tumor margin status and early biochemical recurrence rates seem to be comparable among laparoscopic, robotic, and open series overall (Parsons and Bennett, 2008; Ficarra et al, 2009a; Tewari et al, 2012; Silberstein et al, 2013).

Improvements in the available instruments are highly likely to advance even further the technologic capabilities of surgeons performing LRP and RALP. Equipment expense, especially with RALP, remains a significant issue for some hospitals, and not all may be able to offer this state-of-the-art technology. Nonetheless, there seems to be little doubt that minimally invasive approaches for radical prostatectomy, especially RALP, have become the dominant surgical treatment for localized prostate cancer in the United States and are having continued growth and acceptance worldwide.

Historical Perspective

HISTORICAL PERSPECTIVE

Two major advances in the radiotherapeutic management of adenocarcinoma of the prostate have occurred since the early 1980s. The first advance was the generation of linear accelerators and conformal techniques capable of delivering high doses of radiation deep within the pelvis while simultaneously respecting the normal tissue tolerance of the anterior rectal wall, prostatic urethra, femoral heads, and bladder neck. The second advance occurred when image-guided techniques were introduced for use during the insertion of radioactive sources directly into the prostate gland. Eliminating the former freehand technique has vastly improved the physician's ability to deliver high doses of radiation to the prostate gland while sparing interposed and juxtaposed normal structures. These two advances have increased the therapeutic ratio of radiation therapy (RT) in the management of prostate cancer. Specifically, decreased gastrointestinal (GI) toxicity has been documented (Deamaley et al, 1999) and improved cancer control has been suggested (Pollack et al, 1999).

The physical property that permits the photon radiation generated from a linear accelerator to penetrate deeply and spare normal tissue is the high energy of the beam. As the energy of the beam increases, the beam penetrates deeper before exerting its cytotoxic effect. Whereas orthovoltage and cobalt-60 units deposited their maximum dose within 1.25 cm below the skin surface, high-energy linear accelerators deliver the maximum dose of radiation at more than 15 cm below the skin surface. In addition, the use of multiple and conformal fields, as well as intensity-modulated and image-guided RT (Jani et al, 2003), has minimized the amount of rectum receiving the high-dose radiation volume, leading to lower rates of radiation-induced proctitis (Pollack et al, 1999).

With respect to image guidance and brachytherapy, transrectal ultrasonography (TRUS) has provided an improved monitoring system compared with freehand or fluoroscopically guided radioactive source deposition. Using this image guidance system, geometric feedback on source location within the prostate gland intraoperatively has provided the potential for delivering high doses of radiation within the prostate gland while limiting dose to the prostatic urethra and the anterior rectal wall. The theoretical advantage of brachytherapy is the physical property of rapid dose falloff (a few millimeters) because of the low energy of the radioactive sources used—only 21 and 28 keV for palladium-103 and iodine-125, respectively. This rapid falloff, however, also mandates millimeter precision in the placement of these sources to ensure that the tumor-bearing regions within the prostate gland are not underdosed. These issues are discussed in more detail in the brachytherapy sections.

In brief, the close of the 20th century saw the introduction of three-dimensional, conformal-based, image-guided RT using high-energy radiation beams and image guidance for the placement of permanent radioactive sources into the prostate gland. As discussed

Localized Disease

in this chapter, these advances in the radiotherapeutic management of adenocarcinoma of the prostate provided the basis for improvement in both quality of life and cancer control.

LOCALIZED DISEASE

Pretreatment Prognostic Factors

Recommendations for the treatment of clinically localized adenocarcinoma of the prostate should be made using the results of evidence-based medicine. Pretreatment prognostic factors have established roles in predicting outcome after external-beam RT (EBRT) (Pisansky et al, 1993; Zietman et al, 1994; Hanks et al, 1995; Lee et al, 1995; Zagars et al, 1995; Pisansky et al, 1997). These standard pretreatment factors include **prostate-specific antigen (PSA) level, biopsy Gleason grade, and American Joint Commission on Cancer Staging (AJCC) clinical stage**. Combining these three factors led to a definition of the three risk groups for patients managed with RT who have clinically localized disease. These three risk groups are as follows:

- **Low risk:** More than 85% 5-year PSA failure-free survival, AJCC clinical stage T1c-T2a and PSA level of 10 ng/mL or lower, and biopsy Gleason grade of 6 or lower.
- **Intermediate risk:** Approximately 50% 5-year PSA failure-free survival, AJCC clinical stage T2b or PSA higher than 10 ng/mL but no higher than 20 ng/mL, or biopsy Gleason grade of 7.
- **High risk:** Approximately 33% 5-year PSA failure-free survival, AJCC clinical stage T2c or PSA higher than 20 ng/mL, or biopsy Gleason grade of 8 or more; patients having at least clinical stage T3a disease are grouped with high-risk patients with localized disease.

Figure 116-1 shows 5-year actuarial data for 473 patients stratified using the clinical risk groups based on pretreatment PSA, biopsy Gleason grade, and AJCC clinical stage.

Pretreatment Risk Groups and Prostate Cancer-Specific Mortality

Data (D'Amico et al, 2003) now exist to support the significant association of the pretreatment risk groups and prostate cancer-specific mortality (PCSM) after EBRT, as shown in Figure 116-2. Specifically, in a multi-institutional study of 2370 radiation-managed patients, the relative risk of PCSM for patients with high-risk or intermediate-risk disease compared with low-risk disease was 14.3 (95% confidence interval [CI] 5.2 to 24.0, $p_{\text{Cox}} < .0001$) and 5.6 (95% CI 2.0 to 9.3, $p_{\text{Cox}} = .0012$), respectively. For illustration, Figure 116-3 contains the relative contribution of PCSM and non-PCSM after treatment to all-cause mortality stratified by the patients' age at the time of RT and the pretreatment risk group. These findings

have been validated by others at Johns Hopkins (Hernandez et al, 2007) and the Mayo Clinic (Boorjian et al, 2008).

Further Stratification of Intermediate Risk into Favorable and Unfavorable

The fraction of prostate biopsy samples found to contain prostate cancer is readily available information for all patients with PSA-

detected or clinically palpable prostate cancer. The fraction of positive biopsy results is obtained by dividing the number of positive cores by the number of cores sampled. Studies investigating the ability of the fraction of positive prostate biopsies $\times 100$ (percentage of positive biopsies) to predict pathologic end points after RT suggest a role for this clinical factor in predicting tumor volume (Terris et al, 1995), extracapsular extension (Badalament et al, 1996; Borirakchanyavat et al, 1997), seminal vesicle invasion (D’Amico et al, 1996), lymph node involvement (Conrad et al,

Figure 116-1. Prostate-specific antigen (PSA) failure-free survival stratified by risk group, defined using PSA value, biopsy Gleason grade, and 1992 American Joint Commission on Cancer Staging clinical T stage for 473 patients managed using external-beam radiation therapy. Pairwise, *P* values are as follows: low versus intermediate, *P* = .02; intermediate versus high, *P* = .0004; low versus high, *P* = .0001. bNED, biochemically no evidence of disease; Int, intermediate.

Figure 116-2. Pretreatment risk groups and prostate cancer-specific mortality after external-beam radiation.

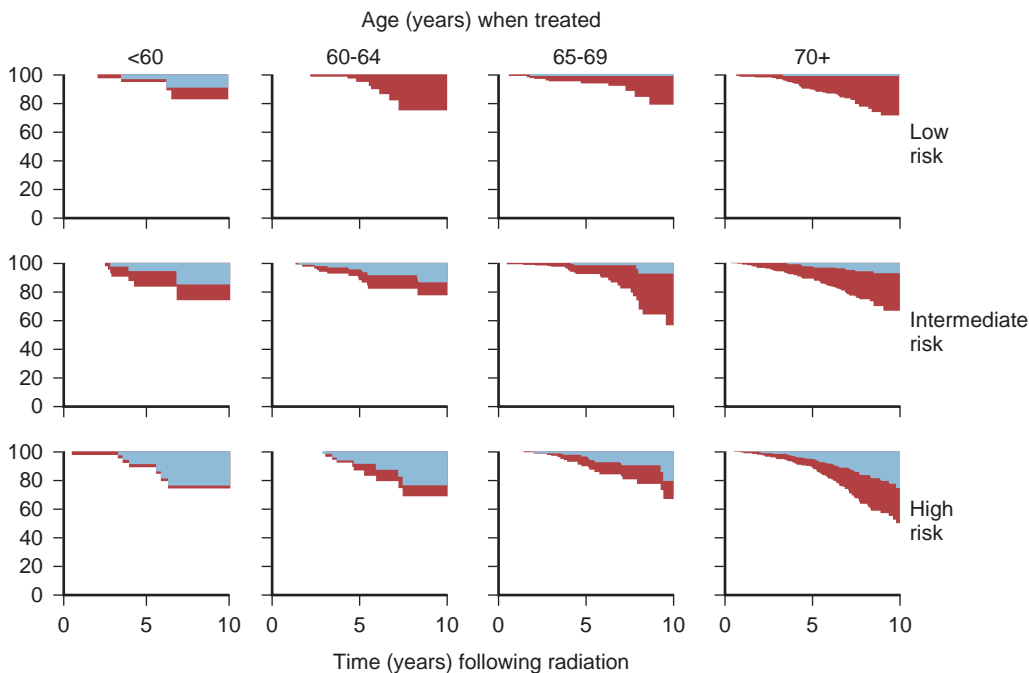

Figure 116-3. Relative contribution of prostate cancer-specific mortality (PCSM) and non-PCSM after treatment to all-cause mortality stratified by the patients' age at the time of radiation therapy and the pretreatment risk group.

1998), and percentage of Gleason grade 4 and 5 disease in the radical prostatectomy specimen (Epstein et al, 1994).

The percentage of positive prostate biopsy specimens has been shown to be an independent predictor of time to postoperative PSA failure after controlling for the established prognostic factors (D'Amico et al, 2000). The percentage of positive prostate biopsy specimens also has been shown to provide information in addition to the known prognostic factors for predicting PSA control after EBRT. Specifically, 473 men treated using three-dimensional (3D) conformal EBRT at the Joint Center for Radiation Therapy between 1989 and 1998 had detected PSA or clinically palpable prostate cancer. Figure 116-1 illustrates the ability of the previously described risk group system (D'Amico et al, 1998b) that was based on pretreatment PSA level, biopsy Gleason grade, and AJCC clinical stage to stratify patients according to PSA outcome. Specifically, 5 years after RT, 91%, 62%, and 43% of low-risk, intermediate-risk, and high-risk patients, respectively, had not experienced PSA failure as defined by the American Society for Therapeutic Radiology and Oncology (ASTRO) Consensus Panel (1997).

Figure 116-4 illustrates the clinically relevant stratification provided by the percentage of positive biopsy results in the previously defined intermediate-risk group on the basis of pretreatment PSA level, biopsy Gleason grade, and AJCC clinical stage. Specifically, patients in the intermediate-risk subgroups who also had less than 34% of the positive biopsy samples improved their risk stratification for PSA outcome by one category to low risk. Conversely, patients with more than 50% of positive biopsy samples performed less well than expected and were comparable with the high-risk patients.

Of particular importance, however, is that the majority of patients (158 of 207 [76%]) in the intermediate-risk group could be classified into either a 30% or an 85% 5-year PSA control high-risk or low-risk cohort, respectively, using the preoperative prostate biopsy data. Therefore, of the 473 study patients, all but 49 (10%) were classified into high-risk or low-risk groups regarding PSA outcome after RT, using the percentage of positive prostate biopsy results, PSA level, biopsy Gleason grade, and AJCC clinical stage.

Additional methods of stratifying intermediate risk into favorable and unfavorable have been proposed. Investigators from MD Anderson performed recursive partitioning analysis to divide radiation-managed intermediate-risk patients into subcategories and found those with Gleason 4+3 or clinical T2c were in an unfavorable group that had a 4.6 times higher risk for clinical or bio-

chemical failure than those with favorable intermediate risk (Gleason 6 and up to cT2b or Gleason 3+4 and cT1c) (Castle et al, 2013). A study from Memorial Sloan Kettering defined unfavorable intermediate risk as any patient having Gleason 4+3 or percentage of positive biopsy results of 50% or greater, or multiple intermediate risk factors (Gleason 7, PSA level of 10 to 20 ng/mL, cT2b/c) and noted a hazard ratio for prostate-cancer mortality of 7.39 ($P = .007$) compared with patients with favorable intermediate risk (Zumsteg et al, 2013).

Of note, a Harvard study also identified having two or more high-risk factors as a way of separating very high risk from standard high risk, with the former having a 4.8 times ($P < .001$) greater risk for prostate-cancer mortality than the latter (Wattson et al, 2012).

Percentage of Positive Prostate Biopsy Results and Prostate Cancer-Specific Mortality in Low-Risk and Favorable Intermediate-Risk Patients

With longer follow-up, the impact of the percentage of prostate positive biopsy findings on prostate cancer-specific mortality in low-risk and favorable intermediate-risk patients has become available (D'Amico et al, 2004). Specifically, from a series of 421 patients with low-risk (PSA ≤ 10 ng/mL and biopsy Gleason score ≤ 6) or favorable intermediate-risk (PSA > 10 to 15 ng/mL or biopsy Gleason score 7, but not both factors) disease who underwent 3D conformal radiation therapy (3DCRT) to a median dose of 70.4 Gy, a significant association between PCSM and the percentage of positive prostate biopsy samples at diagnosis was documented. In particular, the relative risk for PCSM after 3DCRT for patients with 50% or more compared with less than 50% prostate positive biopsy samples was 10.4 (95% CI 1.2 to 87, pCox = .03), 6.1 (95% CI 1.3 to 28.6, pCox = .02), and 12.5 (95% CI 1.5 to 107, pCox = .02) in men with a PSA of 10 ng/mL or less and Gleason score 6 or less, PSA of 10 ng/mL or less and Gleason score 7 or less, and PSA of 15 ng/mL or less and Gleason score 6 or less, respectively. By 5 years after 3DCRT, up to 10% as compared with 2% or less (log-rank $P \leq .01$) of these patients experienced PCSM if they had 50% or more compared with less than 50% prostate positive biopsy samples as shown in Figures 116-5, 116-6, and 116-7. For the purpose of illustration, Figure 116-8 contains the relative contributions of PCSM and non-PCSM after treatment to all-cause mortality stratified by the percent of positive prostate biopsy samples (<50% vs. $\geq 50\%$) and the PSA level and biopsy Gleason score at diagnosis.

Therefore the percentage of positive prostate biopsy results should be considered in conjunction with the PSA level, the biopsy Gleason grade, and AJCC clinical stage at diagnosis when counseling patients with newly diagnosed and clinically localized prostate cancer about both PSA outcome and, more important, the chance of avoiding PCSM after RT.

Pretreatment Prostate-Specific Antigen Velocity and the Risk for Prostate Cancer-Specific Mortality

Studies have documented that a pretreatment PSA velocity greater than 2 ng/mL/year is associated with an increased risk for biochemical recurrence, metastasis, and cancer-specific death after treatment with RT or RT and hormonal therapy (D'Amico et al, 2005; Palma et al, 2008). In particular, in men with otherwise low-risk disease undergoing EBRT, a pretreatment PSA velocity greater than 2 ng/mL/year increased the risk for death from prostate cancer x-fold, which translated into 19% (95% CI 2 to 39) compared with 0% of men dying of prostate cancer within 7 years after treatment with RT if the PSA velocity was more than as compared with 2 ng/mL/year or less, respectively. As a result, such men planning to undergo RT should be considered for RT and hormonal therapy because of the known survival benefit when adding hormonal therapy to RT in men with locally advanced (Pilepich et al, 1995, 1998, 2001; Bolla et al, 2002) or localized high-risk disease (D'Amico et al, 2008).

Figure 116-4. Prostate-specific antigen failure-free survival stratified by percentage of positive biopsies for 207 intermediate-risk patients managed using external-beam radiation therapy. Pairwise, P values are as follows: 34% versus greater than 34% to 50%, $P = .02$; greater than 34% to 50% versus greater than 50%, $P = .06$; 34% versus greater than 50%, $P = .002$. bNED, biochemically no evidence of disease.

Figure 116-5. Prostate cancer-specific mortality following three-dimensional conformal radiation therapy for patients with 50% or more as compared with less than 50% prostate positive biopsy in men with a prostate-specific antigen (PSA) of 10 or less and Gleason score of 6 or less. RT, radiation therapy.

Figure 116-7. Prostate cancer-specific mortality following three-dimensional conformal radiation therapy for patients with 50% or more as compared with less than 50% prostate positive biopsy in men with a prostate-specific antigen (PSA) of 10 or less and Gleason score of 7 or less. RT, radiation therapy.

Figure 116-6. Prostate cancer-specific mortality after three-dimensional conformal radiation therapy for patients with 50% or more as compared with less than 50% prostate positive biopsy and a prostate-specific antigen (PSA) of 15 or less and Gleason score of 6 or less, respectively. RT, radiation therapy.

The Role of Multiparametric Magnetic Resonance Imaging

Multiparametric magnetic resonance imaging (MRI) combines morphologic and functional MRI sequences including T2-weighted, diffusion-weighted, dynamic contrast-enhanced (DCE) and magnetic resonance spectroscopic imaging, and its use in conjunction with an endorectal coil and a higher strength (3 tesla [T]) magnet may have significant prognostic utility. Researchers from the National Cancer Institute (NCI) found a strong correlation between **apparent diffusion coefficients (ADC)** derived from diffusion-weighted imaging and both Gleason score ($P = .003$) and clinical risk group ($P < .0001$) (Turkbey et al, 2011). In addition, in a study of 100 favorable-risk men who received radical prostatectomy, 3T multiparametric endorectal MRI was 75% and 95% accurate at predicting pathologic extracapsular extension and seminal vesicle invasion, respectively (Hegde et al, 2013). Therefore MRI may be a useful tool in further stratifying risk in patients who are borderline between two treatment options, such as intermediate-risk patients considering monotherapy with radiation alone versus combined modality therapy with radiation and short-course androgen deprivation therapy (ADT).

KEY POINTS: PRETREATMENT PROGNOSTIC FACTORS

- Prostate cancer-specific mortality can be estimated on the basis of the pretreatment PSA level, biopsy Gleason score, and clinical T category.
- The percentage of positive prostate biopsy samples, pretreatment PSA velocity, number of unfavorable factors, primary Gleason pattern, and multiparametric 3T endorectal MRI can add additional prognostic information for further stratification of risk, particularly in intermediate-risk disease that is heterogeneous.

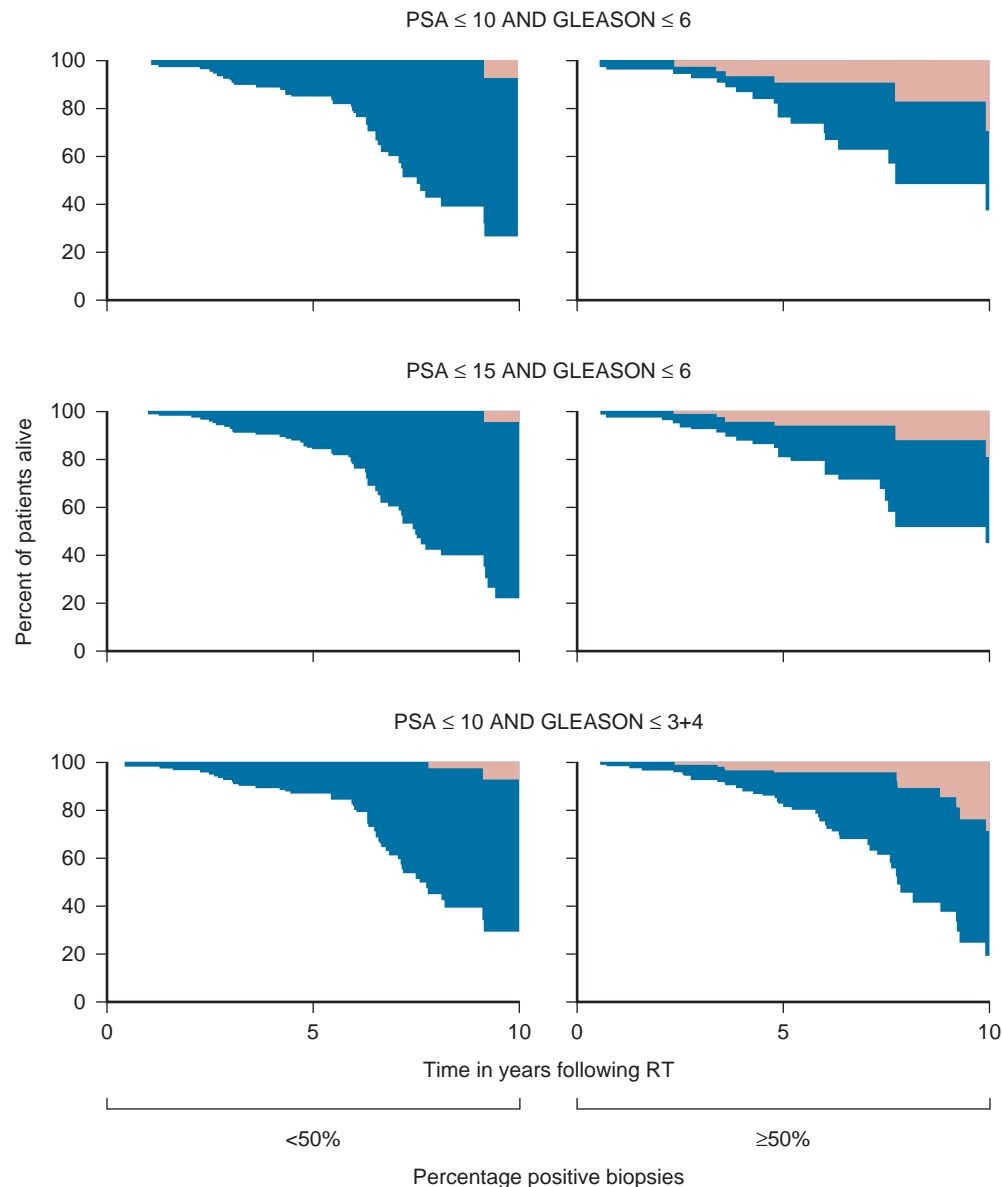

Figure 116-8. Relative contributions of prostate cancer–specific mortality (PCSM) and non-PCSM after treatment to all-cause mortality stratified by the percentage of prostate-positive biopsy (<50% vs. ≥50%) and the prostate-specific antigen (PSA) level and biopsy Gleason score at diagnosis. RT, radiation therapy.

Post-Treatment Prognostic Factors

Localized Disease: Evaluating the Response to Radiation

Prostate-Specific Antigen Follow-up: Definition of Failure.

Serum PSA is widely accepted as a surrogate end point for monitoring the success of definitive treatment for localized prostate cancer. The PSA-based definition of biochemical failure after radiotherapy has evolved over the past two decades. Unlike the situation after radical prostatectomy, residual benign glands may be responsible for a low level of PSA production but an “acceptable” PSA level after successful radiotherapy is markedly lower than the range of normal for an age-matched population because of marked atrophy of non-malignant acini (Grignon and Sakr, 1995).

Ablation of normal prostatic epithelium is dose dependent. Median PSA nadirs range from 0.6 ng/mL after 70 Gy, to 0.3 ng/mL for radiation doses of 79 Gy, to 0.1 ng/mL or less for those receiving EBRT and a brachytherapy boost (Roach et al, 2006). Nadir PSA value is a significant predictor of outcome, but no absolute nadir threshold can or should be used to define cure (DeWitt et al, 2003).

Although a standard definition of failure is essential for the purposes of clinical trials and reporting of data, it must be emphasized that establishing that a patient meets the criteria for biochemical failure is not justification for intervention.

The 1996 ASTRO Consensus Conference (1997) proposed a standardized definition of biochemical failure after radiotherapy. Recognizing that PSA stability after the nadir is important, three consecutive increases in PSA, with backdating of failure to midway between the nadir and the first increase, was proposed. Although the ASTRO definition provided uniformity in reporting of results, it became clear with additional data that it was not an ideal solution to the problem of defining biochemical failure after radiotherapy. Waiting for three rises delays the establishment of failure by 18 months or more (Cherullo et al, 2002), and backdating biases the Kaplan-Meier estimate, an effect that is worse with shorter follow-up (Roach et al, 2006). In addition, the original ASTRO consensus definition of biochemical failure was not predictive of clinical progression or survival and was not developed using data from patients treated with combined radiation and ADT or those treated with brachytherapy.

To address these issues, a second consensus conference was held in Phoenix, Arizona, in 2005, and recommended that the standard definition of **biochemical failure after radiotherapy**, with or without short-term androgen deprivation, be established as a rise of 2 ng/mL or more above the nadir (Roach et al, 2006). Failure is not backdated; if salvage treatment is instituted before meeting these PSA criteria, failure is considered to have occurred at the time of salvage. PSA rises that can be clearly attributed to other causes, such as laboratory error, prostatitis that responds to antibiotics, or a benign PSA bounce that resolves without any intervention in patients treated with brachytherapy, should not be declared as biochemical failures. This definition is known as the “Phoenix” or “nadir + 2” definition. If the original ASTRO consensus definition is used, results should be reported for a timeframe that is 2 years less than the median follow-up of the population. For example, biochemical control could be reported at 5 years for data with a median follow-up of 7 years to minimize the confounding effects of backdating.

Time to Nadir. Serum PSA declines slowly after completion of radiotherapy. Both the level and timing of the nadir have been correlated with distant metastases and cause-specific survival (CSS) (Hanlon et al, 2002; Pollack et al, 2002). Lee and colleagues (1996) reported that 75% of men whose PSA reached a nadir in less than 12 months had distant metastases by 5 years compared with 25% of those whose PSA took more than 12 months to reach a nadir ($P < .001$). Denham and associates (2008) analyzed the results of the Trans-Tasman Radiation Oncology Group (TROG) 9601 trial, which randomized 802 men with locally advanced prostate cancer to 66 Gy of EBRT with 0, 3, or 6 months of ADT. Biochemical failure before 24 months (cut point band < 1.5 years to < 2.5 years) was suggested as a surrogate for CSS. Buyyounouski and colleagues (2008) identified 18 months as the cut point for time to nadir that was optimal as a surrogate for CSS in a population of 211 failures amongst 1174 men treated with 3D conformal radiotherapy. The median dose of radiation was 72 Gy with a range of 67 to 82 Gy. An interval to biochemical failure less than 18 months was independently predictive of distant metastases ($P = .008$) and was the only predictor of prostate cancer-specific mortality ($P = .0003$). The actuarial 5-year distant metastatic rate for biochemical failures occurring before or after 18 months was 52% versus 20% ($P < .0001$), and the actuarial prostate cancer-specific mortality was 36% versus 6% ($P = .0001$).

The previous two reports were based either on “conventional” radiation doses (66 Gy) or a range of doses. Kapadia and associates (2012) studied the interval to biochemical failure for a population of 710 patients treated with dose-escalated radiotherapy in the range of 76 to 78 Gy, with or without ADT. Biochemical failures occurred in 21% and were measured from completion of radiotherapy and/or ADT. Biochemical failure before 18 months (short interval) predicted decreased CSS ($P < .0001$) and overall survival ($P < .0001$). Overall survival at 8 years was 78% for those without biochemical failure, 87% with a long interval to biochemical failure, and 38% with a short interval to biochemical failure ($P < .0001$, hazard ratio [HR] 3.7, CI 2.3 to 5.9). On multivariate analysis, biochemical failure before 18 months increased the risk for prostate cancer death ($P < .0001$) and all-cause mortality ($P = .003$), whereas biochemical failure after 18 months did not.

Significance of Nadir Value and Doubling Time. The level of PSA nadir achieved reflects the dose of radiation and the type of failure. With conventional dose radiotherapy, the median PSA nadir for patients with no evidence of disease (NED) in most series is 0.4 to 0.5 ng/mL (Zietman et al, 1996; Critz et al, 1999; Crook et al, 2000), whereas for those exhibiting local failure it is often greater than 1.0 ng/mL and for distant failure greater than 2 ng/mL. A study by Hanlon and colleagues (2004) ($n = 615$, follow-up median 64 months) reported that freedom from distant metastases was 96% for a nadir less than 1 ng/mL, 89% for nadirs 1.1 to 2 ng/mL, and 61% for nadirs greater than 2 ng/mL. Zelefsky and coworkers (2009) analyzed 844 patients treated with conformal radiotherapy to doses ranging from 64 to 81 Gy. A nadir less than 1.5 ng/mL at 2 years after treatment was predictive for long-term freedom

from distant metastases and prostate cancer mortality. The 10-year rates of distant metastases were 17.5% for men with nadirs greater than 1.5 ng/mL at 2 years compared to 7.9% for nadirs less than 1.5 ng/mL. In a stratified competing risks analysis, nadir PSA greater than 1.5 ng/mL at 2 years was an independent risk factor for distant metastases after adjusting for T stage, Gleason score, preradiotherapy PSA, and radiation dose ($P < .001$).

For patients treated with permanent seed brachytherapy Grimm and associates (2001) found that the lower the PSA nadir, the higher was the probability of success. A PSA nadir less than 0.5 ng/mL is associated with significantly better long-term freedom from biochemical failure (95.2% vs. 71.5%) (Ko et al, 2012). A PSA level at 5 years after brachytherapy is highly predictive of outcome, with 97.4% 10-year biochemical control in a cohort of 921 men with PSA less than 0.2 ng/mL at 5 years after brachytherapy (Ko et al, 2012). Hayden and coworkers (2010) found only one late biochemical relapse among 762 patients with a PSA less than 0.2 ng/mL at 48 to 60 months after implant. Crook and colleagues (2011) reported that with a mean dose to 90% of the prostate of 160 Gy, only 10% of patients at 5 years have a PSA level greater than 0.2 ng/mL, and two thirds of these patients are still showing a decreasing trend. These results are very similar to observations by Stock and associates (2009) in which only 10.9% of 742 patients had a PSA level greater than 0.2 ng/mL at 5 years. The 10-year freedom from biochemical failure was 98% for a 5-year PSA level less than 0.2 and 81% for a PSA level greater than 0.2 ng/mL. Grimm and associates (2001) reported that the proportion of patients with a PSA level less than 0.2 ng/mL continues to increase for up to 7 to 8 years.

The **postnadir doubling time** of the PSA level also correlates with the type of failure, with distant failures having shorter PSA doubling times of 3 to 6 months, whereas doubling times for those with local failures are a year or more. D’Amico and colleagues (2003) reported that a PSA doubling time of less than 3 months is associated with prostate cancer mortality. Doubling time, however, may not be an ideal surrogate end point. The calculation of doubling time depends on the number of values available, being more reliable with a wide range of values (Denham et al, 2008).

Valicenti and colleagues (2006) focused on PSA doubling time in an analysis of the Radiation Therapy Oncology Group (RTOG) trial 9202, which randomized 1514 men with T2c-4 prostate cancer to 65 to 70 Gy of EBRT and short-term neoadjuvant ADT plus or minus 24 months of adjuvant ADT. At 5 years, the actuarial CSS was 84.7% in the cohort of patients with a PSA doubling time less than 12 months compared to 94.3% for longer doubling times (HR 5.63, 95% CI 3.78 to 8.3). PSA doubling time was significantly associated with CSS.

Denham and associates (2008) in the analysis of the previously mentioned TROG 9601 trial used a cut point of PSA doubling time of less than 12 months. For these patients, the HR for prostate cancer death was 23.49 (CI 12.94 to 42.63, $P < .001$). If parameters such as interval to biochemical failure of less than 2 years and PSA doubling time of less than 12 months prove to be successful surrogates for prostate cancer-specific mortality, the required 7 to 8 years of follow-up in a clinical trial may be reduced to 2.5 to 3 years for accurate prediction of the superior treatment arm. Surrogates also may guide management of individual patients, suggesting earlier intervention in those with a PSA doubling time of less than 12 months while increasing the comfort level with continued observation in those with longer doubling times.

The manner in which PSA nadir and time to nadir reflect the type of failure requires explanation. Three sources of PSA potentially contribute to the nadir: residual benign prostatic epithelium, residual local prostate cancer cells, and subclinical disseminated micrometastases. The longer the time to nadir and the lower the absolute nadir, the more likely it is that only benign prostatic epithelium remains, hence the NED status. A higher radiation dose achieves a more complete ablation of normal epithelium and thus a lower nadir. For patients in whom radiotherapy fails to eradicate all the local tumor, the PSA declines progressively until the rate of growth of the surviving prostate cancer cells is greater than the death rate of those fatally damaged by the radiation, at which point the

PSA begins to rise, generally relatively slowly. In the third scenario, subclinical micrometastases continue to grow unchecked despite successful treatment of the primary tumor. This growth rate outstrips the rate of decline in the local tumor population relatively early after treatment, leading to a higher and earlier nadir and a more rapid doubling time.

Neoadjuvant Hormones and the Definition of Biochemical Failure. In the presence of residual benign epithelium or before the full effect of radiotherapy has been expressed, PSA may fluctuate or show several consecutive increases. When neoadjuvant androgen deprivation is used before radiotherapy, patients often start radiotherapy with an already undetectable PSA. If the PSA remains undetectable, it is impossible to determine a true nadir or time to nadir. A substantial proportion of patients treated with EBRT and ADT experience a PSA increase when the testosterone recovers. Zietman and colleagues (2005a) reported that the median time to PSA “bounce” (defined as an increase of 0.2 ng/mL) after EBRT (68.2 to 72 Gy) and ADT was 2.2 years. The median magnitude was 0.9 ng/mL, and 18.6% met the nadir + 2 definition of failure. Subsequently, as the effect of the radiotherapy is expressed, the PSA declines once again. Based on a data set of 1865 men treated with EBRT, Pickles (2006) and coworkers reported a bounce duration of 12.5 months and median height of 0.8 ng/mL, but only 2.1% met the nadir + 2 definition of failure. Interestingly, only 20% of bounces occurred during the testosterone recovery period, with the rest occurring once the testosterone had normalized. This may represent a delayed response to testosterone stimulation or may implicate other causes such as inflammation or instrumentation. Closer follow-up and more frequent PSA testing is more likely to detect PSA fluctuations or bounces. The Phoenix or nadir + 2 definition of failure is associated with fewer false calls of failure than the original ASTRO consensus definition of 3 rises after the nadir.

Brachytherapy and the Benign Bounce Phenomenon. Benign PSA bounces or spikes are a well-recognized phenomenon after prostate brachytherapy. A spike or bounce is most frequently defined as a rise greater than 0.2 ng/mL followed by a durable decline (Critz et al, 2000) and is seen after both low-dose-rate (LDR) and high-dose-rate (HDR) brachytherapy. Overall, approximately 35% of men will experience a PSA bounce of 0.2 ng/mL or greater after LDR brachytherapy (Critz et al, 2000; Merrick et al, 2002c; Ciezki et al, 2006; Toledano et al, 2006; Mitchell et al, 2008; Caloglu et al, 2011; Hinnen et al, 2012), but in younger men the frequency may reach 65% (Gomez-Iturriga et al, 2010). The mean increase is 1 ng/mL but can be up to 10 ng/mL, with 12% meeting the nadir + 2 definition of biochemical failure. Spikes may last as long as 12 to 18 months, and double peaks can be seen. Biopsies performed to investigate the rising PSA may show residual cancer with treatment effect (indeterminate) (Reed et al, 2003). Currently, there is no reliable way to discern whether a rising PSA in the first 3 years after brachytherapy represents treatment failure. Kirilova and associates (2011) investigated patients undergoing a PSA bounce with magnetic resonance spectroscopy and reported a diffuse increase in the ratio of choline to citrate across the gland, rather than a focal phenomenon that might be expected if the PSA increase were associated with tumor activity. It is recommended that a rising PSA within 30 months of brachytherapy be monitored. If the rise approaches 10 ng/mL, systemic staging is warranted, and, if the bounce persists beyond 30 months, a prostate biopsy is warranted. Only patience and careful follow-up demonstrate the subsequent spontaneous PSA decline to low levels.

Postradiation Therapy Biopsy

Although serum PSA nadir has been widely adopted as a surrogate end point to determine treatment efficacy, it cannot distinguish between local and systemic failure. Postradiotherapy prostate biopsies are a logical means of evaluating the local effect of radiotherapy. The major issues involve timing of the biopsies with respect to completion of radiotherapy, interpretation of indeterminate biopsies that show marked radiation effect, and the uncertainty imposed by sampling error.

Timing. In early reports, little was known about the rate of histologic clearance of irradiated tumor and failures were declared as early as 6 months after completion of radiotherapy (Scardino and Wheeler, 1985). It is now recognized that the time for histologic resolution of tumor parallels the time to serum PSA nadir and for the same reasons. Radiation causes postmitotic cell death, and fatally damaged cells may survive a limited number of cell divisions (Mostofi et al, 1992, 1993). Biopsies performed before histologic resolution is complete show a moderate-to-marked radiation effect (Crook et al, 1997a). The ultimate viability of these cells cannot be predicted. Crook and colleagues (Crook et al, 1995) determined that the optimal time to biopsy is 30 to 36 months after radiotherapy.

Interpretation. Gleason scoring of irradiated prostate cancer should be performed only if the histologic evidence of radiation effect is absent or minimal. Gleason’s original work was based on surgically obtained material that had not been exposed to prior radiotherapy or hormonal therapy. It is based on gland architecture, which is known to be markedly altered by radiotherapy. Inappropriate application of the Gleason scoring system to disintegrating malignant glands showing a marked RT effect (Siders and Lee, 1992; Grignon and Sakr, 1995) results in a false-positive biopsy often misinterpreted as high grade and may lead to unnecessary salvage therapy (Reed et al, 2003).

Radiation atypia in benign glands can be severe enough to mimic malignancy (Bostwick et al, 1982; Grignon and Sakr, 1995; Cheng et al, 1999). Anticytokeratin monoclonal antibody for high-molecular-weight keratin labels the basal cell layer of benign glands and therefore helps distinguish radiation atypia in benign glands from residual tumor where the basal cell layer would be absent (Brawer et al, 1989).

Scoring systems for the degree of radiation effect have been proposed (Dhom and Degro, 1982; Bocking et al, 1987) on the basis of cytoplasmic and nuclear changes (Box 116-1) and can be helpful in interpreting the biopsy (Crook et al, 1997b). Their importance is to emphasize the need to differentiate between biopsies showing no or minimal radiation effect and those showing marked treatment effect (Zelevsky et al, 2004). Failure to recognize these differences dilutes the prognostic significance of biopsy status and may lead to

BOX 116-1 Grading Scheme for Cytoplasmic and Nuclear Radiation Effect

The scores for cytoplasmic and nuclear changes are added together. A score of 5 to 6 represents marked treatment effect, 3 to 4 is moderate, and 0 to 2 is minimal.

CYTOPLASMIC CHANGES

- 0 No identifiable RT effect
- 1 Swelling and microvesicular change
- 2 Extensive vacuolation, macrovesicular change, and voluminous cytoplasm
- 3 Indistinct or ruptured cytoplasm or Lipofuscin pigment accumulation or Glands dilated or just single cells with no glandular formation or

NUCLEAR CHANGES

- 0 No identifiable RT effect
- Some swelling or smudging of nuclei but nucleoli still visible or
- Smudged and distorted chromatin or
- Nucleoli rare or absent or
- Large bizarre nuclei or
- Pyknotic small condensed nuclei

RT, radiation therapy.

inappropriate salvage therapy. Immunohistochemical stains for markers of cellular proliferation such as proliferative cell nuclear antigen (Crook et al, 1994; Ljung et al, 1996) and Ki-67 have been used in interpretation of the significance of residual tumor and are associated with subsequent failure (Crook et al, 2000).

Zelefsky and associates (2008b) studied 339 men treated with 3D conformal RT with a median follow-up of 10 years. The 2-year biopsy status was strongly predictive of 10-year biochemical NED rate, freedom from distant metastases ($P = .004$), and CSS ($P = .007$). Importantly, biopsies with marked treatment effect behaved as negative. This was confirmed by Crook and colleagues (2009) in a report on 361 men who participated in a randomized trial of 3 versus 8 months of ADT before conventional EBRT. Biopsies were performed between 24 and 30 months after completion of radiotherapy. In multivariate analysis biopsy status ($P < .0001$) and Gleason score ($P < .0001$) were the two strongest determinants of biochemical disease-free survival.

Imaging and Sampling Error. TRUS alone is of limited diagnostic use after radiotherapy because the increase in fibrosis alters the echogenic characteristics of the irradiated prostate (Crook et al, 1993; Svetec et al, 1998). MRI offers vastly improved soft tissue definition over either computed tomography (CT) or ultrasound. Multiparametric MRI has greater accuracy in the detection of recurrent prostate cancer after radiotherapy than T2-weighted imaging alone. Westphalen and colleagues (2010) reported that the addition of magnetic resonance spectroscopy to T2-weighted imaging in men with suspected recurrence after EBRT increased the area under the receiver operating curve (AUC) to 0.79 from 0.67, detecting recurrence in 37 of 64 men. Donati and associates (2013) compared T2-weighted imaging to T2 with the addition of diffusion weighting (DW) and DCE and found that T2 imaging with DW improved the AUC for two independent readers but that DCE offered no additional benefit in a study of 53 men with suspected recurrence. Arrayeh and associates (2012) reported that preradiotherapy and postradiotherapy endorectal 1.5 T MRI scans in 9 men with local recurrence were able to image the recurrence at the same site as the original dominant nodule, confirmed on whole-mount step-sectioned salvage prostatectomy.

Local therapy should be evaluated in terms of local tumor eradication. Local failures can be reduced by treatment refinements such as dose escalation and improvements in treatment planning and delivery. Systemic failures are a problem of selection of patients and a failure to recognize high-risk features that require a combined modality approach to address a potential systemic component. Postradiotherapy prostate biopsies are fraught with problems of timing, interpretation, and sampling error. Multiparametric MRI is a promising advance in the investigation of patients with suspected recurrence and can be used to guide confirmatory biopsies. Clearly viable residual tumor should be in evidence before considering radical local salvage for radiation failure.

KEY POINTS: POST-TREATMENT PROGNOSTIC FACTORS

- The level of PSA nadir achieved after RT reflects the pattern of failure. Specifically, a nadir greater than 2 ng/mL is associated with distant failure.
- The PSA doubling time after RT also predicts the pattern of failure. Specifically, a PSA doubling time of less than 3 months is almost always associated with distant failure.
- An interval to biochemical failure of less than 2 years and a PSA doubling time of less than 12 months may be surrogates for PCSM.

External-Beam Radiation Treatment

The question of whether the absence or presence of local control of a treated tumor is related to the subsequent development of metastatic disease was explored experimentally as far back as 1970. Mice

with sarcomas of the extremity developed fewer pulmonary metastases if their affected limbs were amputated early in the course of disease (Suit et al, 1970). Given that RT is a local treatment modality, one of the main goals of treatment is local control, with the expectation that only patients who achieved such control could be expected to be cured of their cancer. This principle was first examined in prostate cancer in the 1980s, when a relationship between treatment planning technique and cancer control was demonstrated in the Patterns of Care Studies (Leibel et al, 1984; Hanks et al, 1988). Patient treatment records were reviewed from 163 randomly selected radiation oncology departments located across the United States. Tumor control was better in patients who received higher doses of radiation to larger fields, at the expense of increased complications. These studies sparked an intense interest in and ongoing effort to improve outcomes in men with prostate cancer by providing the best treatment planning and delivery systems possible (Leibel et al, 1994).

Advances in Radiation Technology

Although EBRT has been used for decades to treat prostate cancer, it is still an evolving treatment. Until the 1970s, radiation oncologists had to treat cancers without precise knowledge of their location within the body. Knowledge of normal anatomy, routes of spread of a particular cancer, and limited information from diagnostic radiology were used for treatment planning (Asbell et al, 1980). Radiation oncologists became adept at designing radiation fields on the basis of skeletal anatomy. For the treatment of prostate cancer, the radiation portals were centered on the pubic symphysis and femoral heads. One group designed a rotating platform treatment; men with prostate cancer stood on a small mechanical platform that rotated 360 degrees while the radiation beam was aimed at the level of their pants pockets. This was considered advanced for its time. Later, radiation oncologists learned to use additional tools for treatment planning. The location of the prostate was inferred indirectly by introducing a contrast-filled Foley catheter and rectal tube into the patient. The prostate was assumed to be located in the space between these two organs, as shown in Figure 116-9. As recently as the mid-1980s, this technique was considered state of the art. In this era before CT, radiation treatment technique was sometimes referred to as **conventional radiation**.

The ability to visualize the prostate during radiation treatment planning arrived in the 1990s with the advent of CT scanners and use of CT scans for radiation planning. This was a dramatic breakthrough in radiation treatment for prostate cancer, because it allowed the ability to design radiation beams to directly target the prostate and for the first time accurately calculate doses received by nearby organs such as the rectum and bladder (Mohan et al, 1992; Niemierko et al, 1992). Clinicians knew as early as 1980 that they were making significant errors in field placement without CT data, but limitations in computer hardware and software allowed no solution to the problem (Rosenman et al, 1991; Fraass, 1993). They also knew that radiation doses received by surrounding organs caused morbidity, but had no way to calculate doses received by these organs without CT images for treatment planning. Fortunately, the significant and rapid improvement in computer availability, lowered costs, improved graphics, and rapid computational power has changed forever the field of radiation oncology. Men with prostate cancer are the direct beneficiaries of the new technologies, and prostate cancer is one disease for which the radiation treatment today bears little resemblance to that used as recently as the late 1980s (Fraass, 1995).

Therefore the 1990s began the era of 3D tumor visualization and treatment planning using CT scans. For the first time, the prostate and surrounding structures could be identified with increased precision, and the beam's eye view, a technique allowing visualization of the regional anatomy from the perspective of the beam apertures, enabled the design of plans that could more accurately treat the prostate target while minimizing dose to the surrounding normal tissues. The result is described as 3DCRT because the radiation beams conform to the shape of the treatment target (Fraass, 1995).

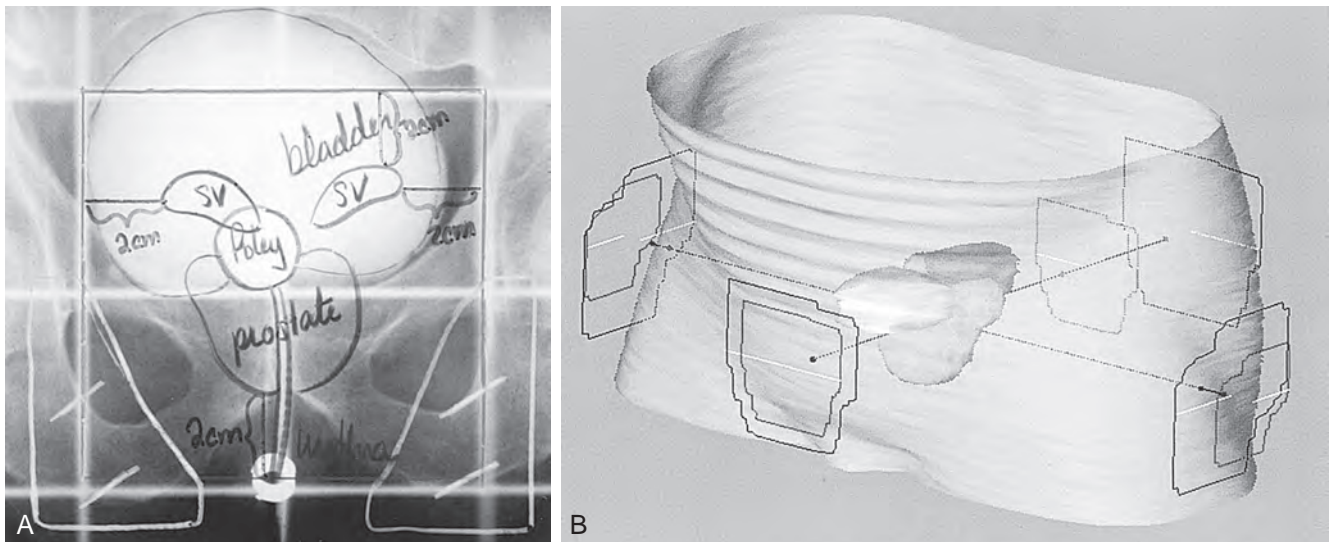

Figure 116-9. A, Conventional radiation therapy treatment portal, anterior view. The location of the prostate is inferred from the location of the Foley balloon and from contrast in the bladder, as well as from the location of the wire anal marker. B, Conformal radiation therapy portal, anterior view. The fully three-dimensional prostate volume is reconstructed from the planning computed tomography scan. SV, seminal vesicles.

One of the goals of conformal prostate radiation is to lower the dose to the surrounding normal tissues, such as the rectum and bladder, while simultaneously increasing the dose delivered to the prostate itself (Burman et al, 1991; Niemierko et al, 1992). All radiation oncologists agree that CT data allowed more accurate placement of the radiation fields. This was first demonstrated by Pilepich and colleagues (1982), who found a 53% error rate in field placement and portal size in patients simulated without CT data. In theory, better pretreatment visualization and localization of the prostate eliminate the need to enlarge the radiation portal to account for anatomic and geometric uncertainties. It follows that smaller radiation portals allow less irradiation of nontarget structures such as the bladder or rectum, thereby reducing treatment-related morbidity.

The ability to accurately calculate radiation doses to the prostate and surrounding organs facilitated further technologic developments that allowed delivery of higher radiation doses to the prostate in an attempt to increase local control and therefore cure rates while simultaneously lowering doses to surrounding organs in an attempt to decrease treatment-related morbidity. A major advance in the delivery of radiation came with the advent of **intensity-modulated radiation therapy (IMRT)**. IMRT is a sophisticated way of treatment delivery in which the intensity of radiation can be varied from each beam angle. IMRT requires the use of advanced software, specialized personnel, and hardware adaptations to linear accelerators (Burman et al, 1997). IMRT uses a new planning approach referred to as *inverse treatment planning*. This approach gives equal attention to the areas where radiation dose is to be minimized (i.e., organs) and the areas that are to receive high-dose treatment (i.e., prostate). With this technology, the prostate can receive a daily dose of 1.8 Gy while the majority of the adjacent bladder receives less than half of this dose. An example of an intensity-modulated beam is shown in Figure 116-10. The tight distribution of radiation around the prostate with avoidance of most of the rectum and bladder is seen on inspection of the figure.

In multiple treatment-planning studies, IMRT consistently demonstrated lowering of radiation doses to the rectum, bladder, femoral heads, and small bowel compared to 3DCRT (Table 116-1). These studies have changed the standard of care in prostate cancer radiation treatment. In 2000, almost every patient with prostate cancer in the United States treated with RT received conformal

Figure 116-10. New intensity-modulated radiotherapy.

radiation; by 2009, almost 100% of prostate radiation was given using IMRT (Sheets et al, 2012).

A more recent and clinically important development was the addition of **image guidance** to prostate cancer RT. Image guidance was development based on a realization that (1) the daily location of the prostate within the pelvis throughout the course of RT is not identical (interfraction motion) (Ten Haken et al, 1991; Beard et al, 1996), and (2) the prostate is mobile even during a single session of RT (intrafraction motion) (Huang et al, 2002). Previously, radiation oncologists expanded the size of the radiation beam (i.e., radiated a larger area around the prostate) to accommodate prostate motion and accepted the risk for increased morbidity. With image guidance, this excessive expansion is no longer necessary because the location of the prostate can be verified daily before delivering radiation. This can be done with a daily ultrasound determination of the prostate location immediately before treatment while the patient is on the treatment table. Another option is to introduce radiopaque ("fiducial") markers into the prostate under ultrasound guidance and to use a commercially available software program to localize the prostate each day before treatment while the patient is on the treatment table. Neither approach, however, addresses the issue of intrafraction motion. One solution to the intrafraction

motion problem is prostate immobilization, which can be achieved using an intrarectal balloon introduced into the rectum and inflated before daily RT. Inflation of the balloon pins the prostate against the pubic bone. Because the immobilized prostate does not move during treatment, small posterior margins can be used (Fig. 116-11), thus minimizing dose to the rectum (Sanghani et al, 2004). Another solution is to use technologies that allow real-time tracking of the prostate, which is possible with the Calypso System (Varian Medical Systems, Palo Alto, CA). The ability to account and correct for uncertainties in the location of the prostate on a daily basis allows for accurate delivery of radiation to the prostate while further lowering incidental doses received by surrounding organs. Therefore image guidance is now a recommended standard of care for prostate cancer RT (National Comprehensive Cancer Network [NCCN], 2012).

KEY POINT: ADVANCES IN RADIATION TECHNOLOGY

- EBRT for prostate cancer has made several significant advances, including CT-based planning in the 1990s, IMRT in the early 2000s, and image guidance more recently.

Tumor Control after External-Beam Radiation Therapy

Because modern RT (IMRT with image guidance as the standard) for prostate cancer looks nothing like RT from the 1990s (pre-CT era) or even early 2000s (pre-IMRT), review of the literature on the efficacy of RT must take into consideration type of radiation used and dose delivered.

Two recently published trials compared RT to conservative management, demonstrating the ability of radiation treatment to improve survival in patients with prostate cancer. In both trials, patients were randomized to ADT with or without EBRT. In a multi-institutional trial sponsored by the National Cancer Institute of Canada (NCIC) and Medical Research Council UK (MRC) (NCIC CTG PR.3/MRC UK PR07), 1205 patients with high-risk or locally advanced prostate cancer were randomized from 1995 to 2005 to lifelong ADT (either bilateral orchiectomy or luteinizing hormone-releasing hormone [LHRH] agonist) with or without RT to 65 to 69 Gy (Warde et al, 2011). The addition of RT significantly improved overall survival: 7-year survival 66% for ADT versus 74% for ADT/RT ($P = .033$). In a Scandinavian trial (SPCG-7/SFUO-3), 875 patients with high-risk or locally advanced prostate cancer were randomized from 1996 to 2002 to lifelong ADT (3 months of combined androgen blockade followed by lifelong flutamide) with or without RT to a median of 70 Gy (Widmark et al, 2009). Again, RT decreased overall mortality: 10-year mortality was 39.4% for ADT versus 29.6% for ADT/RT ($P < .05$). These two trials show that RT improves overall survival in high-risk prostate cancer by an absolute magnitude of 8% (at 7 years) to 10% (at 10 years) compared to ADT alone. Of note, radiation doses used in the modern era for prostate cancer are much higher than those used in these trials and should be even more effective.

That higher dose radiation is more effective than lower dose radiation for prostate cancer was demonstrated by four randomized trials (Table 116-2). In an MD Anderson Cancer Center trial, patients with low-risk (20%), intermediate-risk (46%), and high-risk (34%) prostate cancers were randomized to receive 70 or 78 Gy without ADT (Kuban et al, 2008). Higher radiation dose improved 10-year freedom from failure rate from 50% (70 Gy) to 73% (78 Gy, $P = .004$) (Kuban et al, 2008). Further, this trial demonstrated that the reduction in biochemical failure may translate to a distant metastasis benefit ($P = .059$). The Proton Radiation Oncology Group (PROG) 95-09 trial randomized patients with low-risk and intermediate-risk prostate cancer to 70.2 or 79.2 Gy using a combi-

nation of conformal photon and proton radiation, without ADT (Zietman et al, 2005b, 2010). This trial also found a reduction in 10-year biochemical failure rates associated with higher radiation dose: 32.0% failure (low dose) versus 17.4% (high dose, $P < .001$) (Zietman et al, 2010). Subgroup analysis showed a benefit from higher dose applicable in both low-risk and intermediate-risk patients. A Dutch trial that randomized patients to 68 or 78 Gy included mostly high-risk prostate cancers (56%) (Peeters et al, 2006; Al-Mamgani et al, 2008). Approximately 21% to 22% of patients in each arm received 3 to 6 months of ADT per institutional practice. Higher dose radiation demonstrated improved disease control: 7-year freedom from failure rates were 45% for 68 Gy versus 56% for 78 Gy ($P = .03$) (Al-Mamgani et al, 2008). Subgroup analysis found a benefit from higher dose radiation for intermediate-risk and high-risk prostate cancers. A fourth trial by the MRC (RT01), which randomized patients to 64 or 74 Gy, differed from the others in that all patients received an LHRH agonist that started 3 to 6 months before and throughout RT (Deamaley et al, 2007). This study included a mixture of low-risk (24%), intermediate-risk (32%), and high-risk (43%) patients. Again, high-dose radiation improved biochemical progression-free survival (60% vs. 71% at 5 years, $P < .001$). In subgroup analysis, the benefit of dose escalation was seen in all prostate cancer risk groups.

Taken together, these trials consistently demonstrated improved cancer control outcomes from higher dose radiation which applied to prostate cancer patients in a variety of clinical settings including all risk groups and also with or without ADT. These trials provide level 1 evidence for the use of dose-escalated RT in prostate cancer, which is recommended as a standard of care by current guidelines (NCCN, 2012).

KEY POINTS: TUMOR CONTROL AFTER EXTERNAL-BEAM RADIATION THERAPY

- EBRT improves overall survival compared to conservative management with ADT alone.
- Four randomized trials that consistently showed that higher dose radiation improved disease control have led to the current standard of care, which is to use dose-escalated RT.

TABLE 116-2 Randomized Trials of Lower Dose versus Dose-Escalated Radiation Therapy for Prostate Cancer

STUDY	MEDIAN FU (yr)	PATIENT INCLUSION AND RISK, %	RADIATION TECHNIQUE	TREATMENT ARMS	CANCER CONTROL (%)

Treatment Morbidity and Quality-of-Life Outcomes

These trials also clearly demonstrated the ability of improving radiation technology to lead to better cancer control. For many years, a radiation dose of 70 Gy was considered the maximum that could be safely delivered. With the advent of conformal RT, the ability to visualize and improve targeting of the prostate—and visualize and improve avoidance of surrounding organs—higher dose RT was made possible, with acceptable rates of treatment-related morbidity. However, further studies that demonstrated an association between radiation doses to organs and treatment-related morbidity presented opportunities for further improvement. For example, in the MD Anderson Cancer Center trial, the 5-year freedom from a complication above grade 2 was 26% in the 78-Gy arm and 12% for the 70-Gy arm, nicely demonstrating the relationship that can exist between dose and complications. When further analysis was

performed to identify factors other than total dose that might be used to predict for rectal toxicity, it was shown that the risk for complications increased from 25% to 46% when the rectal volume exposed to 70 Gy increased from less than 25% to greater than 25% (Pollack et al, 2002). Therefore newer technologies such as IMRT that can reduce radiation doses to these organs have the promise of reducing side effects associated with RT, which in general include **GI and genitourinary (GU) toxicity**.

Tables 116-3 and 116-4 summarize acute and late toxicity rates in published series comparing conformal radiation and IMRT for prostate cancer. Consistently in these series, IMRT was associated with lower rates of acute and late GI toxicity, but not GU toxicity, compared to 3DCRT, despite being used to give higher doses to the prostate. Therefore, paradoxically, advances in radiation technology have simultaneously allowed a higher radiation dose to be given while resulting in lower toxicity. The largest series of IMRT patients

is from Memorial Sloan Kettering Cancer Center (Zelevsky et al, 2008c, 2012; Spratt et al, 2013). In this study, 10-year actuarial rates of grade 2 or greater GI toxicity with IMRT to 81 Gy was 5%, with less than 1% of patients developing grade 3 toxicity. In terms of urinary toxicity, 10-year rates of grade 2 or greater toxicity was 20% with IMRT; grade 3 GU toxicity was also rare. In a more recent update of this series, patient outcomes of those who received IMRT with image guidance (implanted fiducial markers) were compared to those who received IMRT without image guidance (Zelevsky et al, 2012). These patients were treated in recent years (2006 to 2009), because image guidance is a relatively new technology. Patients who received IMRT with image guidance had lower rates of late GU toxicity (3-year rates of grade ≥ 2 toxicity: 10.4% with image guidance vs. 20.0% without, $P = .02$), and rates of grade 2 or greater GI toxicity were low in both groups (1.0% vs. 1.6%, respectively; $P = .81$). These studies demonstrate that modern radiation treatment with IMRT and image guidance is safe, with modest rates of acute and long-term treatment-related GI and GU toxicity.

Patient-reported outcomes complement toxicity assessment by physicians to provide a fuller picture of a patient's experience after treatment. In one of the largest modern studies, 292 patients with a median age of 69 years who received either CRT or IMRT were followed prospectively using the validated instrument Expanded Prostate Cancer Index Composite (EPIC) (Sanda et al, 2008). Patients reported acute urinary and bowel symptoms that recovered over time. For example, at 2 months after RT, 12% of patients reported dysuria (compared to 1% at baseline), 23% weak stream (13% baseline), and 34% urinary frequency (16% baseline); symptoms improved by 6 months and were back to baseline levels by 12 months. Urinary incontinence was uncommon after RT. Acute bowel symptoms included urgency (18% at 2 months compared to 3% at baseline) and frequency (16% at 2 months compared to 2% at baseline), which partially recovered with longer time points of assessment. Patients also reported sexual dysfunction after RT in this older patient group. By 24 months after treatment, 60% of patients reported poor erections (compared to 37% at baseline); however, decline in sexual function was mostly from patients who received radiation in combination with ADT, whereas sexual function decline was more modest in patients who received RT alone. Patient-reported outcomes of modern IMRT with image guidance have not been well studied and should be better than these results and others in the literature of patients treated with conformal radiation or IMRT without image guidance.

With advancing radiation technology, which can reduce incidental radiation doses to the bladder and rectum, radiation-associated GU and GI toxicity and impact on patient-reported outcomes have declined over time. However, the anatomic structure causing radiation-associated erectile dysfunction is not known. Published reports suggest that erectile dysfunction after radiation is caused predominantly by vascular damage, and some data suggest that dose to the penile bulb may be correlated with erectile dysfunction (Roach et al, 2000; Fisch et al, 2001; Merrick et al, 2001). Further studies are needed; once an anatomic structure can be identified, radiation techniques can be used to minimize dose to this structure in an attempt to better preserve patient sexual function.

KEY POINT: TREATMENT MORBIDITY AND QUALITY-OF-LIFE OUTCOMES

- IMRT provides the ability to deliver higher doses of radiation with lower rates of GI toxicity.

Heavy Particle Beams

Since the 1950s, radiation oncologists have used particle beam therapy for their patients with cancer. The common application of

Figure 116-12. Proton beam therapy. (Courtesy Anthony Zietman, Massachusetts General Hospital.)

particle therapy is with the electron beam, which is created by all modern linear accelerators. Other particles such as protons, neutrons, helium ions, heavy ions (neon, argon, carbon), and negative ions are available as well. These **heavy particle beams** are difficult to produce and to control but have certain theoretic advantages over conventional x-ray and **electron beams**. They are more densely destructive in tissue, and the damage they create is less easily repaired by tumor cells. In addition, they travel differently in tissue and exhibit a **Bragg peak**, which refers to a sharp cutoff in dose at the end of the particle's range in tissue (Fig. 116-12). Beyond this depth, the tissue receives little or no radiation. Thus, with appropriate focus and application, it can be easier to spare the normal tissues surrounding the cancerous target.

The most commonly used particles are neutrons and protons. The RTOG sponsored a phase III trial in 1977 (Lawton et al, 1991) in which 91 patients with prostate cancer were randomly assigned to receive treatment with neutrons or conventional radiation (photons). At 10 years, survival was better in the neutron arm (46%) than in the photon arm (26%). However, patient characteristics were not equally balanced between the two arms. Poor prognosticators such as stage D1 disease were more common in the photon arm, and the observed survival difference between the two groups may have been due to this aspect more than to any therapeutic benefit of neutrons per se. However, the data were compelling enough to lead the NCI to fund the construction of several state-of-the-art neutron beam facilities. Again, trials were undertaken to study the efficacy and morbidity of neutron treatment. Because today's cyclotrons are large and extremely expensive, there are few national facilities using neutron beam treatment for cancer patients. In the mid-1980s, a second prospective randomized trial was undertaken by the RTOG. A group of 178 patients with prostate cancer were randomly assigned to receive either neutron beam or conventional photon treatment. The local control rate was higher for the patients who received neutron therapy than for those who received photons (89% vs. 68%), as was the 5-year rate of freedom from PSA failure (83% vs. 55%). However, survival rates were no different in the two arms. Morbidity was higher in patients who received neutron beam treatment and was described as severe in 11% compared with 3% for those who underwent photon irradiation.

In general, acceptance of neutron beam therapy by radiation oncologists has been limited because of the perception that complication rates are high without much gain in tumor control, as well as because of the limited availability and expense associated with neutron production. Over time, a form of conformal neutron beam therapy was developed and became possible in several centers (Forman et al, 1995). At Wayne State University, 300 patients were entered into a phase III trial and randomly assigned to conformal neutron therapy followed by standard CRT or CRT followed by a neutron therapy boost. A statistically significant difference in 5-year disease-free survival was seen for patients treated with neutrons first (93% compared with 73%, $P = .008$) (Forman et al, 2002). Treatment-related morbidity was the same for both groups in this study. A larger retrospective review from the same group of neutron therapy and photon CRT revealed a statistically significant improvement in 5-year relapse-free survival for the group that received neutrons as any component of their therapy. The effect was most pronounced for high-risk patients who had a 35% 5-year relapse-free survival rate versus 7% in the photon-only group ($P = .0004$). Although these data are provocative, one criticism is that the relapse-free survival in the photon-only group from Wayne State is much lower than that of other series reporting on the same population of patients.

Despite the data from Wayne State, most radiation oncologists believe that neutron beam therapy causes greater normal tissue damage than photon beam therapy. Investigators from the Catholic University of Louvain, Belgium, used a mailed questionnaire to assess quality-of-life changes in 262 patients who received mixed neutron-photon irradiation. Of the 230 patients who replied, 22% had four or more bowel movements per day. Retaining stool was a problem in 26% of the patients, and only 38% reported full bowel continence. The patients in this trial received neutron beam therapy using equipment that was not conformal. These data were sufficiently concerning to close their program and demonstrate the importance of up-to-date equipment and technology for the delivery of neutron beam therapy. Today, few patients with prostate cancer in the United States are treated with neutron RT.

Proton beams are also used to treat cancer. Although proton radiation is not a new treatment for prostate cancer, there has been significant recent interest in its use for prostate cancer (Zietman, 2007; MacReady, 2012). Protons are charged particles generated by

a linear accelerator, cyclotron, or synchrotron. Protons have the same theoretic advantage over photon as neutrons (i.e., they are more densely ionizing in tissue and have a sharp dose fall-off in tissue; see Fig. 116-11). In the 1980s, a prospective randomized trial was undertaken in men with locally advanced prostate cancer (Shipley et al, 1995). Patients treated with proton beams had a 95% incidence of clinical local control at 5 years, compared with a 64% incidence for those treated with photons. Although no grade 3 to 5 toxicities were reported in either arm of this trial, grade 1 and 2 rectal bleeding rates were higher in the proton group (32% vs. 12%, $P = .002$), as were urethral strictures (19% vs. 8%, $P = .07$). When the group with rectal bleeding was carefully analyzed, a relationship between the volume of rectum treated and the dose of protons given was established and guidelines were developed for future trials (Hartford et al, 1999).

Studies comparing proton therapy to modern IMRT for prostate cancer are mostly limited to treatment-planning studies, which have shown that proton radiation can reduce the volumes of nearby organs that receive low to medium—but not high—doses of radiation compared to IMRT (Table 116-5). For example, in a study by Trofimov and associates (2007), proton plans to 79.2 cobalt Gray-equivalent (CGE) were created for 10 patients using parallel opposed lateral fields, a commonly used technique for prostate cancer (Trofimov et al, 2007). They noted that proton therapy allowed a smaller proportion of the rectum to receive low doses of radiation (<30 CGE) compared to IMRT. However, proton plans did not reduce the volume of rectum receiving high doses of radiation. Another study by Vargas and colleagues (2008), using two proton beams but with angles optimized to minimize rectal and bladder dose, similarly demonstrated a reduction in rectal volume receiving low-to-moderate radiation doses, but minimal benefit in the volume of rectum receiving high-dose radiation (Vargas et al, 2008). Studies that found improvements in rectal sparing with proton therapy tended to find improvements in bladder sparing as well. Again, the most significant benefit was in reducing the volume of bladder receiving low-to-medium doses, but not high doses (Mock et al, 2005; Trofimov et al, 2007; Vargas et al, 2008; Chera et al, 2009). The study by Trofimov and associates (2007) reported better bladder sparing by proton therapy at doses lower than 30 CGE compared to IMRT, but protons actually resulted in a higher volume of the bladder receiving a high dose of 70 CGE (17% for proton vs. 11% for IMRT).

*Statistically significant difference.

IMRT, intensity-modulated radiation (photon) therapy; LN, lymph nodes; SV, seminal vesicles.

Similarly, [Vargas and colleagues \(2008\)](#) found bladder sparing at doses from 10 to 35 Gy, but not at doses above 60 Gy. The opposed lateral beam arrangement used in proton therapy raises concern over the dose received by femoral heads. Several studies identified similar or worse femoral head dose distributions using protons compared to IMRT, especially when pelvic nodes are included in the treatment target as reported by Chera and coworkers (mean femoral dose 31 CGE for proton vs. 22 Gy for IMRT) ([Mock et al, 2005](#); [Trofimov et al, 2007](#); [Chera et al, 2009](#)). However, the femoral doses delivered in these studies remained lower than the commonly accepted dose constraint of 45 Gy.

Whether the lowering of low-to-moderate doses of radiation to the rectum from proton therapy results in lower GI toxicity rates compared to IMRT is unknown; conversely, it is unknown if proton causes higher rates of GU toxicity or pelvic fracture rates as a result of somewhat higher doses to the bladder (at high dose regions) and femoral heads. To date, no clinical study has directly compared patient outcomes of proton therapy versus modern IMRT. Available studies include single-arm (proton therapy) series mostly from single institution or a few institutions ([Slater et al, 2004](#); [Coen et al, 2011](#); [Mendenhall et al, 2012](#)). These data suggest that proton therapy is safe and effective for prostate cancer treatment and likely results in cancer control and morbidity outcomes similar to that with IMRT. Because proton-beam treatment units are extremely expensive to construct and operate, proton therapy represents an expensive treatment option for prostate cancer that currently has not demonstrated a clinical benefit over standard IMRT.

KEY POINT: HEAVY PARTICLE BEAMS

- No clinical study has directly compared patient outcomes of proton therapy versus IMRT for prostate cancer.

Brachytherapy

Brachytherapy (“short” therapy) is the placement of radioactive sources into or near tumors for therapeutic purposes. The discovery of x-rays and the purification of radium in the early 20th century paved the way for the development of this form of therapy. Subsequent technical advances and refinements led to the increasingly accurate techniques currently in use, which are associated with greater efficacy and lower cost and morbidity rates. Since the early 1990s, the number of patients undergoing brachytherapy for early-stage prostate cancer has increased dramatically. The CaPSURE database reported an increase in the use of brachytherapy from 4% in 1990 to 15% by 2007 ([Cooperberg et al, 2010](#)).

Pasteau and Degrais described the temporary placement of radium-containing needles into the prostate through the urethra ([Pasteau, 1913](#)). During the 1920s, [Young \(1922\)](#) at Johns Hopkins performed prostate brachytherapy using intracavitary radium sources in the bladder, rectum, and urethra “cross-firing” into the prostate. This technique was refined at Memorial Hospital in New York by Benjamin Stockwell Barrington, who pioneered implanting needles containing radioactive radon gas into the prostate by a transperineal approach. During the 1970s, [Whitmore and colleagues \(1972\)](#) at Memorial Sloan Kettering in New York performed ^{125}I implantation in patients after they underwent lymph node dissection. The prostate was exposed by the retropubic approach for implantation. However, this “freehand” technique resulted in suboptimal distribution of seeds and poor dosimetry ([Zelefsky and Whitmore, 1977](#)).

[Holm and colleagues \(1983\)](#) described closed transperineal implantation with the aid of TRUS. With this approach, the needles used to insert the radioactive seeds could be visualized, with an improvement in the accuracy of seed placement compared with the retropubic approach. Surgical morbidity and cost were reduced. For this procedure, the patient is placed in the high lithotomy position

to maximize the transperineal exposure of the prostate. A transrectal ultrasound probe is then inserted and affixed to a mount or stabilizer through a stepping device. A template with a predrilled pattern of parallel holes is attached to the stepper. This permits accurate and reproducible imaging of the prostate throughout the procedure. The template pattern also can be superimposed over the ultrasound image by computer software in the ultrasound device. Needles of 17 or 18 gauge are inserted through the template into the prostate. The position of the needle tip can be confirmed by transverse or parasagittal imaging. Sealed metallic seeds containing the radioactive isotope are deployed as the needle is withdrawn ([Figs. 116-13 through 116-16](#)).

Computer programs using sophisticated algorithms to optimize dosimetric coverage of the entire prostate while minimizing dose to the intraprostatic urethra and rectum have been developed. [Stone and Stock \(1999\)](#) determined the number of seeds to be implanted on the basis of the size of the gland and the nomogram reported by [Anderson \(1976\)](#). The seeds are implanted using the empirical

Figure 116-13. Patient in the high lithotomy position with the transrectal ultrasound probe fixed to the stepper device. Needle containing radioactive seeds is implanted through the perineum using a grid system.

Figure 116-14. Transverse ultrasound image of the prostate. Several seeds are visible in the anterior gland. The arrow delineates the target location for the insertion of a needle.

Figure 116-15. Parasagittal ultrasound image of the prostate. The arrow demonstrates that the needle depth goes to the prostatic capsule before deployment of the radioactive seeds.

Figure 116-16. Intraoperative fluoroscopic image of the prostate demonstrating the placement of palladium-103 seeds.

rules defined by Patterson and Parker in the 1930s (Fletcher, 1980), preferentially sparing the urethra to reduce urinary morbidity (Wallner et al, 1995). Several methods for designing seed placement are currently in use for permanent radioactive seed implantation. The method popularized by Blasko and colleagues (1993) in Seattle uses preimplant transrectal ultrasound images obtained through a separate procedure with the patient in the same lithotomy position to calculate seed placement for an optimal dosimetric plan. Kaplan and coworkers (2000) described a method in which the dosimetric plan is calculated intraoperatively. Other methods for seed implantation using CT (Koutrouvelis, 1998) and an intraoperative MRI device (D'Amico et al, 1998a; Susil et al, 2004) also have been described. Cystoscopy is often but not always performed and can be useful to retrieve any loose seeds or blood clots from the bladder.

TABLE 116-6 Ideal Permanent Prostate Brachytherapy Postimplantation Guidelines

ORGAN	PARAMETER	CONSTRAINT
Prostate	Dose received by 90% of the prostate volume (D90)	>100% of prescription dose
	Volume of the prostate that received 100% of the prescription dose (V100)	>95% of the prostate
	Volume of the prostate that received 150% of the prescription dose (V150)	<50% of the prostate
Rectum	Volume of the rectum that received the prescription dose (R100)	<2 cm ³

Modified from Salembier C, Lavagnini P, Nickers P, et al; GEC ESTRO PROBATE Group. Tumour and target volumes in permanent prostate brachytherapy: a supplement to the ESTRO/EAU/EORTC recommendations on prostate brachytherapy. *Radiother Oncol* 2007;83:3–10.

Isotopes

There are several choices for isotopes for permanent seed implantation. ¹²⁵I emits low-energy x-rays at 27 keV, with a half-life of 59.6 days. The use of ¹⁰³Pd was introduced in 1986 because it has an energy spectrum similar to that of ¹²⁵I, with 21-keV x-rays, but with a significantly shorter half-life of 17 days. Higher activity seeds are required for ¹⁰³Pd versus ¹²⁵I to deliver a similar tumoricidal dose (i.e., 1.3 to 1.5 mCi per Pd seed vs. 0.4 to 0.5 mCi per I seed). The recommended monotherapy dose prescription for ¹²⁵I is 140 to 160 Gy and for ¹⁰³Pd is 110 to 125 Gy. When brachytherapy is combined with EBRT, brachytherapy doses ought to be lower (108 to 110 Gy for ¹²⁵I and 90 to 100 Gy for ¹⁰³Pd) (Davis et al, 2012).

Assessment of Permanent Implant Quality

The goal of prostate brachytherapy is to deliver a homogeneous dose to the prostate while minimizing dose to nearby sensitive normal structures such as the rectum and urethra. Postimplant dosimetry in these dose-limiting regions is important to assess implant quality. Postimplantation CT with or without MRI is performed to determine seed localization and reference the dose to the prostate and other structures of importance (Willins and Wallner, 1997; Mizowaki et al, 2002). A significant source of error in these calculations is prostatic edema, which is invariably observed after implantation (Prestidge, 1998; Waterman et al, 1998). Although clinical practice varies with postoperative imaging taking place between day 0 and day 60, early imaging/dosimetric calculation must consider the effect of postoperative edema. The American Brachytherapy Society (ABS) recommends using the D90 (the minimal dose covering 90% of the prostate volume) and the V100 and V150 (the percent volume of the prostate receiving 100% and 150% of the prescribed dose, respectively) as parameters to assess implant quality (Davis et al, 2012). Ideal implant parameters are shown in Table 116-6.

High-Dose-Rate Brachytherapy

Permanent seed implantation delivers a dose over a number of weeks to months depending on the isotope chosen, hence the term *low dose rate*. An alternative method of brachytherapy, which delivers short but high doses of radiation using temporary catheters, is **HDR brachytherapy**. For HDR brachytherapy, hollow catheters are placed through the perineum into the prostate and imaged using the same procedure as for LDR brachytherapy. A treatment plan is developed based on the use of a 1 to 10-curie iridium-192 source

that emits 400-keV gamma radiation and can be migrated along the length of each catheter at various positions for variable lengths of time on the order of seconds to minutes. The source is manipulated robotically to minimize radiation exposure to medical staff. The radiation dose is delivered in this way over several applications. No postimplantation dosimetry is required. HDR has been used primarily as a boost in combination with EBRT for patients with intermediate-risk or high-risk features, although it is becoming more common as monotherapy in patients with low-risk disease.

Outcome of Implants

Post-treatment biopsies can be used to assess the efficacy of local therapies to control cancer, but there are several limitations to using this technique in prostate cancer, which were discussed earlier within this chapter. Early studies of prostate brachytherapy included postimplantation biopsy; these studies showed a very low rate of 4% to 5% positive biopsy results 2 years after good dosimetry implants (Prestidge et al, 1997; Stone et al, 2004). More recently biochemical surrogates for cancer control have been used in addition to survival parameters.

Serum PSA is the most useful marker to assess relapse. A rising PSA level after irradiation predicts local or distant relapse, or both, often many years before clinical evidence of recurrence (Kaplan et al, 1993). However, the variability of PSA, especially at low levels, often makes interpretation problematic. In addition, the suppres-

sion of PSA with even short courses of antiandrogen therapy can complicate interpretation of results. A PSA bounce has been reported in approximately 30% of patients after brachytherapy (Critz et al, 2000; Hinnen et al, 2012). Some investigators have reported improved rates of cancer control in patients who experience a PSA bounce (Patel et al, 2004; Hinnen et al, 2012).

Table 116-7 summarizes the clinical outcomes of permanent implant monotherapy in several large series. Although these are retrospective single-institution studies (with the exception of RTOG 98-05), they represent results from a uniform population of patients. These results compare favorably with those of similarly selected patients treated with EBRT or radical prostatectomy (D'Amico et al, 1998b; Quaranta et al, 2004; Grimm et al, 2012). Early results with HDR used as monotherapy for patients with low-risk prostate cancer have demonstrated acceptable toxicity and early rates of biochemical freedom from relapse similar to those for permanent seed implants. Table 116-8 summarizes results of trials of HDR monotherapy.

Brachytherapy Combined with External Irradiation

Although outcomes in patients with low-risk prostate cancer using brachytherapy are excellent, biochemical control can be improved for intermediate-risk and the higher risk subset of intermediate-risk patients by combining brachytherapy with EBRT. EBRT is employed in these patients to treat the prostate and periprostatic tissues. This

*Includes higher risk.

†Includes some intermediate-risk patients.

strategy allows targeting of high-risk areas outside the prostatic capsule and increases the dose to the prostate itself. Typically, a dose of 4500 cGy of EBRT is delivered (compared with 7560 to 7920 cGy when EBRT is used alone). The dose of the implant boost in such combination therapy is generally 60% to 70% of the dose prescribed for patients treated with implant alone. Biochemical disease-free survival for high-risk men using this strategy can range from 80% to 90%, particularly when combined with androgen deprivation (Koontz et al, 2009; Taira et al, 2010; Merrick et al, 2011; Shilk-rut et al, 2013a, 2013b). HDR brachytherapy series with at least 5 years of follow-up also show very good biochemical control for both intermediate-risk (83% to 100%) and high-risk (74% to 91%) patients (Morton and Hoskin, 2013). The role of external beam with permanent seed brachytherapy versus brachytherapy alone for selected intermediate-risk men is being investigated in a randomized clinical trial by the RTOG (RTOG trial 0232).

Toxicity

Implant techniques and quality have a strong impact on the likelihood of radiation toxicity from prostate brachytherapy. Age, existing comorbid diseases such as peripheral vascular disease or diabetes mellitus, and tobacco use also may predispose to increased toxicity from treatment.

Determining incidence rates and severity of treatment-related morbidity also depends on the instrument used and how the information is gathered. The American Brachytherapy Society proposed as a minimal set of assessment criteria the International Prostate Symptom Score (IPSS) for assessing urinary function, the International Index of Erectile Function for erectile function, and RTOG toxicity grading criteria for rectal toxicity.

Urinary Toxicity

The IPSS tends to increase significantly immediately after implantation and then decrease, at a rate depending on the half-life of the isotope used (Sanda et al, 2008; Kollmeier et al, 2012). For HDR, brachytherapy appears to show a similar pattern with 15% to 18% showing grade 2 or greater acute urinary symptoms (Zamboglou et al, 2013). In recent series of permanent implants, the rate of chronic grade 2 or greater urinary toxicity is approximately 20% (Mohammed et al, 2012; Buckstein et al, 2013). The use of α -blockers before implantation may decrease the severity and duration of urinary symptoms (Merrick et al, 2002b). Wallner and colleagues (1995) reported the risk for urinary toxicity to be a function of the length of the urethra receiving a high dose. Grade 2 to 3 morbidity was observed when 20 mm + 11 mm of the urethra received more than 400 Gy with ^{125}I implants. Larger prostatic volumes—specifically, glands greater than 60.0 cm³—also were associated with higher rates of urinary toxicity. Terk and colleagues (1998) reported on 251 patients using the IPSS to assess urinary function before and after ^{125}I or ^{103}Pd implantation. Patients with a pretreatment IPSS above 20 demonstrated a 29% risk for developing urinary retention, and a pretreatment score less than 10 was associated with only a 2% risk. Although data are yet maturing, HDR brachytherapy appears to be very well tolerated, with low rates of chronic grade 3+ urinary morbidity (5% to 10%) (Barkati et al, 2012; Zamboglou et al, 2013).

Brachytherapy after TURP is associated with increased risk for urinary incontinence. Although this complication is quite uncommon in men without any preexisting urethral trauma (~3%), Mock and colleagues (2013) reported a 19% incidence in patients with one previous TURP and up to 53% in those with a history of multiple procedures (although numbers were small). Overall, significant postbrachytherapy obstructive symptoms refractory to medical management occur in approximately 2% to 3% of patients.

Rectal Toxicity

Acute minor rectal symptoms secondary to brachytherapy are usually self-limiting. Late rectal toxicity—specifically, rectal bleed-

ing secondary to radiation proctitis—can be a minor, self-limiting side effect of radiation or a major toxicity requiring surgical intervention such as argon plasma coagulation (Smith et al, 2001) or, in the worst cases, diverting colostomy. The rate of rectal bleeding after implant therapy has been reported to be approximately 1% (Zelevsky et al, 1999; Mohammed et al, 2012). The incidence of all significant rectal complications has been reported to be 1% to 2% (Barkati et al, 2012; Zamboglou et al, 2013). A postimplantation colostomy rate of 0.3% was observed in a study of Medicare claims (Benoit et al, 2000a, 2000b). The rate of rectal complications is correlated with the dose and the length of rectum receiving a high dose. For example, rectal complications have been observed more frequently when 17 mm² (± 5 mm) of the rectal wall received more than 100 Gy (Wallner et al, 1995). Wallner and colleagues (1995) accordingly recommended minimizing the amount of rectum receiving 100 Gy in ^{125}I implants. Merrick and colleagues (2003) reported that rectal complications were rarely observed when the rectal wall received 85% of the prescribed dose.

Potency

Impotence is defined by the National Institutes of Health (NIH) consensus on erectile dysfunction (ED) as the “inability to attain and maintain a penile erection sufficient to permit satisfactory sexual intercourse” (NIH Consensus Conference, 1993). The cause of implant-related ED is multifactorial. Factors such as underlying small vessel disease, cavernous nerve damage, and dose to the vascular tissues surrounding the penile bulb have been implicated in postimplantation ED (DiBiase et al, 2000; Merrick et al, 2001).

In any case, potency preservation rates for patients undergoing implantation are superior to those reported for patients receiving prostatectomy, EBRT, or neoadjuvant hormonal therapy/EBRT/brachytherapy boost (Sanda et al, 2008). Snyder and colleagues (2012) reported that 5 years after treatment potency was maintained in 76% of patients undergoing brachytherapy compared with 71% receiving EBRT plus brachytherapy, and 58% in those undergoing EBRT, brachytherapy, and androgen deprivation.

Potters and colleagues (2001) reported a 5-year potency maintenance rate of 76% with brachytherapy monotherapy and 56% with combined external beam and brachytherapy boost. The addition of hormones to external beam and brachytherapy boosted lower potency rates to 52%. Age was a significant prognostic factor in a univariate analysis (Merrick et al, 2002a), and the addition of external beam and a history of diabetes mellitus were significant factors in a multivariate analysis (Robinson et al, 2002). In a meta-analysis, the probability of maintaining potency at 1 year after treatment was 76% (69% to 82%) with brachytherapy monotherapy and 60% (48% to 73%) with external beam with brachytherapy boost (Robinson et al, 2002). When the probability of ED was adjusted for age, the difference between prostate brachytherapy and prostatectomy increased (Robinson et al, 2002).

Sildenafil citrate and other phosphodiesterase-5 inhibitors have been reported effective in 74% to 81% of patients who avail themselves of oral therapy for ED (Merrick et al, 2003; Raina et al, 2003).

KEY POINTS: BRACHYTHERAPY

- Prostate brachytherapy can be delivered as monotherapy for low-risk prostate cancer or in conjunction with EBRT (with or without ADT) for intermediate-risk and high-risk prostate cancer.
- Dose delivered to the rectum is directly related to the likelihood and degree of late morbidity from brachytherapy.

Hypofractionation and Stereotactic Body Radiotherapy

Fractionated radiotherapy has been used since the early days of radiation, when it was found that cure could be achieved with less

normal tissue injury when the radiation dose was split into many small fractions (Coutard, 1932). Standard fractionation for prostate cancer is 1.8 to 2 Gy per day. Moderate **hypofractionation** uses doses of 2.4 to 4 Gy per day, and extreme hypofractionation uses doses of 6 to 10 Gy per fraction (Cabrera and Lee, 2013). When doses in this range are given, treatment is often delivered less than 5 days per week to allow normal tissue recovery. An entire treatment course of extreme hypofractionation can be completed within 2 weeks.

Radiobiology of Hypofractionation

The rational basis for the use of hypofractionation for prostate cancer lies in the radiobiology and slowly proliferative nature of prostate cancer cells. Prostate cancer is believed to be acutely sensitive to the amount of radiation delivered at each treatment, such that providing a few treatments of high dose is more effective at producing cell kill than many fractions of 2 Gy. It is hypothesized that one could provide a lower total dose, thus lessening risk for normal organ injury, with similar prostate cancer control using higher than standard doses per fraction (Withers, 1985).

The support for this hypothesis is based on clinical studies in which the treatment dose was varied. The first report suggesting this relatively unique sensitivity to high dose per fraction was by Brenner and Hall (1999), who used the 3-year freedom from biochemical failure rates of 134 patients receiving permanent brachytherapy and 233 patients receiving EBRT to calculate an **alpha-to-beta ratio** of 1.5 Gy. This radiobiologic value is used to calculate the radiosensitivity of a tissue. For comparison, the alpha-to-beta ratio of head and neck cancers is thought to be between 13 and 16 Gy, whereas a late responding skin fibrosis has an alpha-to-beta ratio of 1.7 Gy (Zeman, 2009). Although intriguing, this study brought criticism for its use of several radiation modalities, which vary not only in dose per fraction but also in other radiobiologic qualities of the radiation delivered. However, more recent studies using large cohorts treated with EBRT only continue to support the premise of prostate cancer sensitivity to high dose per fraction. Dasu and Toma-Dasu (2012) evaluated the Phoenix-defined 5-year biochemical control from 11,330 patients treated with EBRT, accounting for overall treatment time, and found that, depending on risk category, the alpha-to-beta ratio varied from 1.0 to 1.7 Gy. A second study found an alpha-to-beta ratio of 1.4 Gy using 5969 patients receiving EBRT (Miralbell et al, 2012). Table 116-9 illustrates how hypofractionation may provide a greater effective dose to the prostate than to normal tissues.

Stereotactic Body Radiotherapy

Although prostate cancer's low alpha-to-beta ratio supports treatment with a few large fractions, care still must be taken to protect

the nearby bladder and rectum, which also are relatively sensitive to high dose per fraction. Thus the advent of extreme hypofractionation was concurrent with technology that provides high accuracy and conformality to the radiation dose cloud. **Stereotactic body radiotherapy (SBRT)** defines an external-beam RT that delivers a high dose each treatment using precisely targeted and highly conformal radiation. The total treatment length is between 1 and 5 fractions (Benedict et al, 2010). Recent linear accelerator technology making SBRT possible includes accurate 2D and 3D imaging of patients immediately before/after and even during treatment, improved dose calculation software, and intensity modulation. SBRT can be performed in a **traditional linear accelerator** or using a **CyberKnife system** (Accuray, Sunnyvale, CA), which is a megavoltage linear accelerator mounted on a robotic arm with six degrees of freedom in conjunction with intrafraction imaging capabilities to track target motion (Kilby et al, 2010).

Understanding of tumor and critical organ motion is essential to designing safe and effective SBRT plans. The prostate is a mobile structure within the pelvis, its position changing in relation to rectal and bladder filling (Schild et al, 1993; Adamson and Wu, 2009). For RT, two types of motion have been defined, interfraction motion, which encompasses changes in prostate position from one day to the next, and intrafraction motion, describing motion of the prostate during each treatment.

Patient positioning and treatment devices are helpful to minimize both types of motion. There appears to be no significance whether the patient is positioned supine or prone (Stroom et al, 1999; Wilder et al, 2010). However, use of an endorectal balloon can reduce prostate variability, particularly intrafraction motion (van Lin et al, 2005; Both et al, 2011). Other techniques that allow adjustment of the patient on the treatment equipment include implantation of permanent nonradioactive fiducial markers that are visible on kilovoltage imaging through the linear accelerator (Aubin et al, 2003; Middleton et al, 2011). This allows the treatment positioning to be corrected to the position of the prostate at that time (Fig. 116-17) (Schallenkamp et al, 2005). Further development of this concept has resulted in the use of implanted electromagnetic wireless transponders that work similar to fiducials but can provide intrafraction monitoring of prostate motion (Willoughby et al, 2006; Quigley et al, 2009). These transponders are larger than fiducial markers and typically require transperineal placement.

Finally, two imaging modalities have been used to document prostate location immediately before treatment delivery each day: **ultrasound** and **CT**. Transabdominal ultrasound imaging with a full bladder uses software to modify patient position on the linear accelerator to match the setup at time of planning (Trichter and Ennis, 2003). Use of this technology requires specialized training and can have significant interuser variability (Langen et al, 2003; Pinkawa et al, 2008). CT imaging uses a cone-beam technique allowing the kilovoltage extension of a modern linear accelerator to obtain a broad-beam CT image of a limited size (Barney et al, 2011). Again, software is used to adjust patient positioning to match the prostate position at planning. The disadvantage to the cone-beam CT technique is the additional dose received by the patient (van Zijteld et al, 2010).

Outcomes for External-Beam Hypofractionation

The evidence for prostate SBRT is still evolving. Five phase III trials of moderate hypofractionation (Table 116-10) have been published, and several more are pending.

A multi-institutional noninferiority trial from the NCIC randomized 936 predominantly low-risk men to 66 Gy in 2-Gy fractions over 6.5 weeks versus 52.5 Gy in 2.625 Gy over 4 weeks (Lukka et al, 2005). Median follow-up was 5.7 years. The 5-year risk for biochemical or clinical failure was 53% in the standard fractionation arm and 60% in the hypofractionated arm (difference -7%, 90% CI -12.6% to -1.4%). Although acute toxicity was slightly higher with hypofractionation (11.4% vs. 7%, difference -4.4%; 90% CI -8.1% to -0.6%), late toxicity was low for both arms (3.2%). The major weakness of this trial was the low dose used for

TABLE 116-9 Examples of Alpha-to Beta Principle for Prostate, Bladder, and Rectum

TISSUE OF INTEREST	ALPHA-TO-BETA RATIO (Gy)	EQUIVALENT DOSE IN 2-Gy FRACTIONS OF 37.5 Gy IN 5 FRACTIONS (Gy)
Prostate cancer	1.5	96
Rectum/bladder	3	79
Bladder	5	67

The biologically effective dose provided in 2-Gy fractions is shown calculated using the alpha-to-beta ratio. Although the rectum and bladder also can have temporary acute effects, only the alpha-to-beta ratio for the chronic late effects is provided. Time delay was not considered in equivalent dose calculation. Current standard dosing using intensity-modulated radiation therapy has shown acceptable safety profile up to 81 Gy in 2-Gy fractions (Van der Kogel, 2002; Alicikus et al, 2011).

both arms that resulted in high failure rates. It was designed before development of the alpha-to-beta ratio hypothesis, and the hypofractionated dose was biologically less effective than the standard arm using an alpha-to-beta ratio of 1.5.

Yeoh and colleagues (2011) reported a randomized trial of 217 cT1-2 patients comparing 64 Gy in 2-Gy fractions over 6.5 weeks

to 55 Gy in 2.75-Gy fractions in 4 weeks. Median follow-up was 90 months and showed improved 7.5-year biochemical relapse-free survival in the hypofractionated arm (34% vs. 53%, comparatively, $P < .05$). Although this study offers support for the rationale of hypofractionation, the numbers are small and the total doses are again low.

A randomized controlled trial from Italy compared 85 men receiving 80 Gy in 40 2-Gy fractions over 8 weeks with 83 men receiving 62 Gy in 20 fractions of 3.1 Gy over 5 weeks (Arcangeli et al, 2012). All were high risk and received 9 months of ADT. With median follow-up of 70 months, 5-year freedom from biochemical failure was similar in both arms (79% vs. 85%, respectively, $P = .065$). Both arms were well tolerated, with GI/GU late toxicities occurring in 16% to 17% and 11% to 14%.

Pollack and colleagues (2011) reported the results of the Fox Chase randomized study of 303 men with intermediate-risk or high-risk cancer. Standard fractionation was 76 Gy in 2-Gy fractions versus 70.2 Gy in 2.7-Gy fractions. There were no significant differences in 5-year biochemical failure (15% vs. 19%, $P = .342$) and worse late grade 2+ GU toxicity in the hypofractionated arm (18% vs. 8%, $P = .028$).

The last published randomized trial of moderate hypofractionation comes from MD Anderson Cancer Center (Cabrera and Lee, 2013). This study randomized 204 predominantly low-risk and intermediate-risk men to 75.6 Gy in 1.8-Gy fractions or 72 Gy in 2.4-Gy fractions. With a median follow-up of 4.7 years, 5-year freedom from biochemical failure was not significantly different ($P = .23$) between standard fractionation (92%) and hypofractionation (92%). Toxicity was likewise similar, although there was a trend toward worse late GI toxicity with hypofractionation ($P = .058$).

Studies of extreme hypofractionation are as of yet early phase I/II studies. However, to date 10 different series of patients treated with 6.7 to 10 Gy per fraction have been published (Table 116-11). Although follow-up is generally short, biochemical outcomes for low-risk and intermediate-risk prostate cancer range between 90% and 100%. However, there is a marked increase in late morbidity compared to studies of moderate hypofractionation, with grade 2 urinary toxicity in some studies greater than 30%. Although it is a rare occurrence, one study did note a grade 4 rectal ulcer in a patient receiving 50 Gy in 5 fractions (Boike et al, 2011) and another reported a rectal fistula (Loblaw et al, 2013).

Ongoing studies will provide more information about the role and risk of hypofractionation. Three multi-institutional phase III noninferiority trials of moderate hypofractionation have recently completed or are actively enrolling. Dearnaley and colleagues

(2012) reported early toxicity data from the Conventional or Hypofractionated High-dose Intensity Modulated Radiotherapy in Prostate Cancer study (CHHiP) study, showing late grade 2+ GI and GU toxicities for both conventional and hypofractionated IMRT. The RTOG completed enrollment of RTOG 0415, a noninferiority trial of low-risk men randomized to 73.8 Gy in 1.8-Gy fractions or 70 Gy in 2.5-Gy fractions. RTOG also has a randomized phase II trial comparing two hypofractionated regimens, 51.6 Gy in 12 fractions with 36.25 Gy in 5 fractions. The Prostate Fractionated Irradiation Trial (PROFIT) through the Ontario Clinical Oncology Group completed accrual of their noninferiority trial comparing 78 Gy in 2-Gy fractions with 60 Gy in 3-Gy fractions. Finally, there is one phase III trial of extreme hypofractionation, the Swedish ISRCTN 4590531, which randomizes intermediate-risk men to 78 Gy in 2-Gy fractions with 42.7 Gy in 6.1-Gy fractions.

The use of moderate hypofractionation for postoperative radiotherapy has been studied, which reduces the length of treatment without significantly increased morbidity. Kruser and colleagues (2011) treated 108 men with 65 Gy in 2.5-Gy fractions. Freedom from biochemical failure at 4 years was 67%. Late grade 2 GU and GI toxicity occurred in 15% and 4%, respectively, with no higher grade toxicities reported. Another study reported the outcomes of 61 men treated to 50 to 52.5 Gy in 20 fractions. Three-year disease-free survival was 74% with low toxicity profile (Lee et al, 2004). Further studies in this area are warranted.

KEY POINTS: HYPOFRACTIONATION AND STEREOTACTIC BODY RADIOTHERAPY

- Hypofractionation reduces the overall treatment course by delivering higher doses per fraction. Safe treatment delivery requires accurate patient setup and conformal treatment planning.
- Doses in the range of 2.6 to 3.1 Gy have been delivered in phase III trials with low morbidity. Patient risk selection and biologically effective doses have resulted in excellent biochemical control reported up to 5 years, but it is not clear if moderate hypofractionation is more efficacious.
- Early studies of extreme fractionation (6.7 to 10 Gy) show good biochemical control rates but the duration of follow-up is limited. Toxicity rates vary. Larger phase III trials are needed.

Radiation Therapy and Androgen Suppression Therapy

Androgen Suppression Therapy and Radiation

Among strategies to improve outcome for patients with intermediate-risk to higher risk prostate cancer, hormonal manipulation in combination with RT has demonstrated improvement in treatment

outcome compared with standard-dose radiation alone. As outlined in Table 116-12, trials have investigated radiation alone versus radiation in combination with androgen suppression as well as the duration of hormonal therapy with the radiation. A meta-analysis of prospective trials of androgen deprivation in nonmetastatic prostate cancer showed a 30% reduction in relative risk for prostate cancer-specific mortality and a 14% reduction in the relative risk for all-cause mortality with the use of ADT (Nguyen et al, 2011).

Androgen Suppression Therapy and Localized Disease

Several prospective randomized studies have investigated the role of androgen deprivation with radiation for men with intermediate to higher risk localized prostate cancer relative to radiation alone (D'Amico et al, 2008; Denham et al, 2011; Jones et al, 2011; Pisansky et al, 2013). Using between 3 and 8 months of androgen suppression, studies have typically shown an advantage to the addition of hormonal therapy in both overall and prostate cancer-specific survival.

The TROG performed a three-arm randomized trial comparing RT alone to RT plus 3 or 6 months of androgen suppression for 818 men with T2b to T4 disease (Denham et al, 2011). With 10.6 years of follow-up, the 6-month arm showed significant improvements in disease-free, metastasis-free, prostate cancer-specific, and overall survival relative to RT alone. D'Amico and colleagues (2008) studied 206 men, all with clinical T1/2 disease and followed for a median of 7.6 years. Their median PSA was 11 ng/mL, and 73% had a Gleason score of 7 or greater. Benefits in both overall and cancer-specific survival were noted. Of note, it appeared that the survival benefit may have been limited to only those men with no or minimal comorbid illness. RTOG 94-08 randomized 1979 men with T1b to T2b and PSA less than 20 ng/mL disease to RT alone versus RT with 4 months of combined androgen blockade (Jones et al, 2011). With a median follow-up of 9.1 years, the 10-year overall survival was 62% in the arm with androgen suppression compared to 57% in the RT alone arm. In unplanned subgroup analyses, it appeared that the 54% of men with intermediate-risk disease derived the greatest benefit with the low-risk group (35%) showing no significant benefit to hormonal therapy.

Androgen Suppression Therapy and Locally Advanced Disease

In RTOG 86-10, 456 patients with large (25 cm³), stage T2b to T4, Nx tumors randomly assigned to 4 months of total androgen suppression with RT given after the first 2 months had improved local control, disease-free survival, and freedom from metastases compared with patients receiving 65 to 70 Gy of RT alone (Roach et al, 2008). At a median follow-up of over 12 years, the 10-year overall survival rates were no different between the two arms but there was a significant improvement in disease-specific mortality of 36% versus 23% ($P = .01$).

In EORTC 22863, a phase III trial of androgen suppression, Bolla and colleagues (2010) reported an overall survival advantage for patients receiving 3 years of goserelin starting at the initiation of RT over RT to 70 Gy alone (Bolla et al, 2010). More than 90% of the 415 patients had either T3 or T4 disease, and the remaining were eligible owing to high-grade tumors. With 9.1 years of follow-up, there were significant improvements in both overall survival and CSS to the addition of androgen suppression.

Two multicenter randomized trials investigated the question of whether the addition of RT improved outcomes for men with locally advanced, localized disease receiving lifelong androgen suppression (Widmark et al, 2009; Warde et al, 2011). In the first, 875 men with a PSA of 70 ng/mL, N0, M0, and mostly T3 disease were randomized to 3 months of combined androgen blockade followed by lifelong flutamide with or without 70 Gy of RT. After a median of 7.6 years of follow-up, Widmark and colleagues (2009) reported a relative risk for cancer-specific death of 0.44 (95% CI 0.30 to 0.66, $P < .001$), favoring the addition of RT. In the second study, 1205 men with mostly T3 and T4 disease were randomized to lifelong

androgen suppression with or without 65 to 69 Gy of RT. With a median of 6 years of follow-up, Warde and colleagues (2011) reported a hazard ratio of 0.54 (95% CI 0.27 to 0.78) for CSS. The overall survival at 7 years was 74% (95% CI 90 to 78) for the combined arm versus 66% (95% CI 60 to 70) for the arm with androgen suppression alone.

Duration of Androgen Suppression

The optimal type, timing, and duration of androgen suppression in combination with RT remain to be defined. In RTOG 99-10, which randomized 1490 men, 84% of whom had intermediate-risk disease, to 4 versus 8 months of neoadjuvant and concurrent androgen suppression with radiation, no advantage was identified in biochemical control or overall survival to longer course treatment (Pisansky et al, 2013).

Several studies investigated duration of androgen suppression among men with higher risk disease. In RTOG 92-02, 1521 patients with stage T2c-T4, N0-1, M0 disease were randomly assigned to 4 months of total androgen suppression with radiation administered after 2 months or the same regimen followed by an additional 2 years of goserelin (Horwitz et al, 2008). A hypothesis-generating subgroup analysis revealed significant improvement in overall survival, 80% versus 69%, and disease-specific survival, 90% versus 78%, in patients with Gleason grade 8 to 10 tumors.

The EORTC randomized 970 men who had received 6 months of combined androgen blockade and RT to no further androgen suppression versus 30 months of an LHRH analogue (Bolla et al, 2009). Powered as a noninferiority study, at 6.4 years of follow-up, the 5-year cause-specific mortality was 4.7% (95% CI 2.7 to 6.7) versus 3.2% (95% CI 1.6 to 4.8), favoring long-term hormonal therapy.

In a study investigating RT with 18 months relative to RT with 36 months of goserelin for men with T3/T4, PSA greater than 20 ng/mL, or Gleason 8-10 disease, Nabid and colleagues (2013) reported that with 6.5 years of follow-up, the 5-year overall and CSS was not statistically different between the two arms. Additional follow-up will be needed to determine whether 18 months is noninferior to 36 months.

Should Pelvic Lymph Nodes Be Treated?

The question of timing of hormonal therapy and impact of radiation field size was addressed by RTOG 94-13, a four-arm study comparing whole-pelvis versus small-field radiation with 4 months of either neoadjuvant or adjuvant total androgen suppression. Eligible patients had adverse risk factors, with estimated risk for positive-node disease of more than 15%. A difference was initially seen in progression-free survival at 4 years, 54% versus 47% for the whole-pelvis versus prostate-only radiation, respectively ($P = .022$), but no difference was seen in overall survival (Roach et al, 2003). An update of this study showed a loss of this benefit in biochemical control, highlighting the need for additional studies investigating the inclusion of nodal volumes in men with a high risk for lymph node involvement (Lawton et al, 2007).

KEY POINTS: RADIATION THERAPY AND ANDROGEN SUPPRESSION THERAPY

- Randomized controlled trials have shown a survival benefit to the combination of radiation and hormonal therapy relative to either radiation or hormonal therapy alone for men with intermediate-risk to high-risk disease.
- For men with locally advanced, high-risk disease, 28 to 36 months of hormonal therapy appears superior to 4 to 6 months and the addition of radiation to lifelong hormonal therapy alone improves survival.
- For men with localized or locally advanced, intermediate-risk disease, 4 to 6 months of hormonal therapy improves survival relative to standard-dose radiation alone.

Radiation Therapy for Palliation
Bone Metastases

In advanced prostate cancer, bone metastases are a common problem (Abrams et al, 1950; Gilbert and Dagan, 1976). Many therapies are available for the management of bone metastases, including surgery, medical management, and radiation. RT can treat most patients with highly effective symptom relief.

The hallmark of osseous metastases is localized pain, which is frequently continuous and unrelenting regardless of the site. The pain caused by bone metastases is not well understood but is likely a combination of direct action of tumor on bone, interactions of the tumor and its secreted factors with nerves in the periosteum, and action of inflammatory cells in the local bone metastasis environment (Peters et al, 2005; Joyce and Pollard, 2009; Jimenez-Andrade et al, 2010). The most serious complication of osseous metastases is spinal cord compression, which is discussed later.

Most bone metastases can be diagnosed by physical examination, plain radiographs, and bone scan. CT and MRI are sometimes required if there is suspicion of bone involvement, but x-ray and bone scans are negative if there is soft tissue involvement. A review of the currently available data on the use of externally applied radiation from prospective studies has shown overall response rates ranging from 85% to 100% using various treatment schedules (Madsen, 1983; Price et al, 1988; Cole, 1989). A single-fraction regimen (800 cGy × 1) appears to be as effective as other, more protracted regimens, is more cost-effective and less time-consuming for patients, and should be the preferred regimen for patients with uncomplicated nonspinal bone metastasis (Wu et al, 2003). A historically important and still frequently used regimen in the United States is 3000 cGy in 10 divided fractions, which provides adequate pain control for most osseous metastases but is not more effective than a single 800-cGy fraction.

Metastasis to a weight-bearing region raises many concerns. A pathologic fracture can be painful and disabling, both functionally and psychologically. Radiographic and clinical factors that warrant consideration of prophylactic surgical fixation include the following (Lane et al, 1980):

- An intramedullary lytic lesion 50% or greater of the cross-sectional diameter of the bone
- A lytic lesion involving a length of cortex equal to or greater than the cross-sectional diameter of the bone or greater than 2.5 cm in axial length

These patients should be evaluated by an orthopedic surgeon. If a pathologic fracture has occurred in a weight-bearing region, surgical fixation is required for pain control and to promote adequate healing. In all situations, postoperative radiation is required. Because prostate cancer produces primarily blastic metastases, pathologic fracture is correspondingly infrequent.

Spinal Cord Compression

Spinal cord compression is a medical emergency. Failure to diagnose and treat promptly can lead to significant morbidity, including paraplegia and autonomic dysfunction. The predominant symptom of cord compression is pain, which occurs in approximately 95% of patients (Gilbert et al, 1978). Pain usually precedes a diagnosis

TABLE 116-14 Clinical Efficacy and Toxicity of Radionuclides Reviewed

RADIONUCLIDE	RESPONSE RATE (%)	RESPONSE DURATION (mo)	TOXICITY
Phosphorus-32	60-80	≈5	++
Strontium-89	60-90	≈6	+
Rhenium-186	75-80	1-2	+
Samarium-153	75-90	2-3	+

of spinal cord compression by approximately 4 months. Symptoms, however, can progress rapidly to neurologic dysfunction in a matter of hours to days. When a patient has progressed to paraplegia, return of function is infrequent. Therefore early diagnosis and therapy are critical. The diagnostic tool of choice to evaluate spinal cord compression is MRI.

Once the diagnosis of spinal cord compression is made, the physician is left with the dilemma of how to treat. There are a few instances in which surgery should be considered as an option before radiation, including pathologic fracture with spinal instability or compression of the spinal cord by bone, unknown tissue diagnosis, or history of previous radiation to the same area.

When the diagnosis of cord compression is made or even suspected, all patients should receive corticosteroid therapy (e.g., dexamethasone). Steroids can decrease vasogenic edema and provide striking analgesic benefit. The loading dose of dexamethasone (Decadron) is 4 to 10 mg, followed by a maintenance dosage of 4 to 24 mg every 6 hours.

Systemic Radionuclide Therapy

The first report on the use of **systemic radionuclides** for the treatment of bone metastases was published by Pecher in 1942. Tables 116-13 and 116-14 provide a summary of the physical characteristics, and the clinical usefulness of the radionuclides are discussed. Historically, radioisotopes such as strontium-89 and samarium-153 have been the mainstay of systemic radionuclide therapy for men with castrate-resistant prostate cancer who have multiple, painful bone metastases. Although effective in providing substantial pain relief in a majority of patients, these agents also tend to suppress blood counts as a result of concomitant irradiation of bone marrow (Porter et al, 1993; Sartor et al, 2004).

A search for isotopes with similar palliative effects but fewer side effects ensued. The clinical development of radium-223 is a result of this search.

Clinical Experience with Radium-223

In 2013, the U.S. Food and Drug Administration approved ²²³Ra for use in men with castrate-resistant and painful bone metastasis who also have no soft tissue metastasis. This approval was based on a prospectively randomized study that found that six cycles of ²²³Ra

provided an increased time to first symptomatic skeletal event and, importantly, prolonged survival (from 11.3 to 14.9 months) compared to best standard of care (Parker et al, 2013).

By selective uptake in bone and the very short distance (<1 mm) over which the charged particle (i.e., alpha particle) acts, damage to surrounding hematopoietic tissues was minimal. In fact, there were no substantive differences in grade 3 or 4 adverse events between patients treated on the ^{223}Ra arm compared to those on the placebo arm. Taken together, these data support the incorporation of this agent as part of the management protocol for men with metastatic castrate-resistant prostate cancer, and, given the safety profile, Ra has the potential for use earlier in the natural history of metastatic prostate cancer.

KEY POINTS: RADIATION THERAPY FOR PALLIATION

- Spinal cord compression, bone metastasis, and pathologic fractures are conditions that require EBRT for palliation.
- Multiple, symptomatic bone metastasis can be treated with systemic radioisotopes.

Molecular Therapies and Radiation for Prostate Cancer

Given that nearly 50% of men with locally advanced prostate cancer will have a biochemical recurrence within 10 years of treatment (Bolla et al, 2002), new technologies that improve the therapeutic index of RT for local disease have the opportunity to significantly affect morbidity and mortality of prostate cancer. Ideally, these molecular-based therapies target vulnerable aspects of the cancer growth or the ability of the cancer to repair injury but do so in a targeted fashion so as to minimize effects on normal, noncancerous tissues.

Targeted RNA-Based Therapy

Ionizing radiation of mammalian cells causes multiple types of cellular injury, of which DNA double strand breaks are considered the most cytotoxic (Smith et al, 1999). Naturally occurring mutations in genes that sense or repair DNA damage are associated with increased sensitivity to irradiation (Helleday et al, 2007; Pollard and Gatti, 2009). Chemical or short-interfering RNA (siRNA) inhibition of DNA repair proteins, such as DNA-dependent protein kinase ATM, also results in cellular hypersensitivity to irradiation (Collis et al, 2003). Although these approaches have potential, they lack a means to selectively target cancer cells to avoid sensitization of surrounding noncancerous tissues.

RNA interference (RNAi) is a promising new therapeutic approach, but the challenge for translating RNAi therapy is delivery, particularly for specific cell types. One developing delivery approach is RNA aptamers, which are nuclease-stabilized targeting molecules capable of binding ligands in much the same way as antibodies (Dausse et al, 2009). Targeted RNA aptamers to the prostate-specific membrane antigen (PSMA) have been developed (Lupold et al, 2002), which are capable of targeting drugs, nanoparticles, and toxins to PSMA expressing prostate cancer cells and tumors (Farokhzad et al, 2004; Cheng et al, 2007). When conjugated to siRNAs and short-hairpin RNAs (shRNAs), these PSMA aptamers are also capable of delivering cell-selective gene knock-down (McNamara et al, 2006; Dassie et al, 2009). Because PSMA is highly expressed in nearly all localized prostate tumors (Sweat et al, 1998; Perner et al, 2007), it is likely that PSMA-targeted aptamer-shRNA chimeras could be employed to inhibit DNA-repair pathways in prostatic cells to enhance radiation-induced cell death in locally advanced prostate cancer. Experiments in animal models have revealed that PSMA-targeted aptamer-siRNA chimeras can target human prostate cancer cells, resulting in knock-down of target mRNA, and target protein, all culminating in more than a threefold increase in tumor growth delay after a single 6-Gy fraction of

radiation. Importantly, there was no evidence of off-target effects or nonprostate cancer radiosensitization (Ni et al, 2011). These data are provocative and support planned clinical translation.

Immunotherapy

Defects in major histocompatibility complex class I expression have been noted in 85% of primary prostate cancers and essentially all metastatic tumors (Blades et al, 1995). As with other tumors, these data suggest that evasion of host immunity may be a critical factor in prostate cancer development. Strategies designed to improve tumor antigen presentation to the host immune system are termed *cancer vaccines* and frequently employ targeted expression of cytokines in tumor cells. This approach results in improved cancer cell vaccine antigen presentation and activation of antigen-presenting cells, both of which are necessary to effect a cellular immune response. A number of cytokines have been tested for their efficacy in inducing an antitumor immune response (Dranoff et al, 1993). Granulocyte-macrophage colony stimulating factor (GM-CSF) has emerged as the most potent cytokine for activation of antigen processing and presentation by dendritic cells (Cella et al, 1997). When tumor antigens are presented in the context of high-level cytokine expression, cytotoxic T lymphocyte-based antitumor immune responses can be enhanced.

It has been suggested that therapies such as radiation can result in the presentation of tumor-associated antigens, which subsequently enhance vaccine-based immunotherapies. One such study using an autochthonous murine model of prostate cancer tested whether radiation in combination with a GM-CSF-based vaccine could augment the CD4 T-cell response (Harris et al, 2008; Wada et al, 2013). Although vaccine alone or radiation alone was not capable of priming an antitumor T-cell activation, the combination of radiation with vaccine substantively enhanced antitumor T-cell activation. This effect was dependent on the relative timing of radiation and vaccination. An interesting clinical trial that tested this general concept also has been completed (Gulley et al, 2005). In this phase I study, a PSA-targeted vaccine and radiation were used to treat men with localized prostate cancer. The combination resulted in significant T-cell responses in the majority of treated patients. These studies and others offer the promise of combination therapies that have both local and systemic anticancer potential.

The monoclonal antibody, ipilimumab, was found to target and block an immunologic checkpoint on T cells called cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) (reviewed in Pardoll, 2012). It is known that CTLA-4 blockade can result in tumor regression and increased survival in patients with advanced melanoma (Hodi et al, 2010). Very interestingly, it was recently reported that a patient with advanced, metastatic melanoma who was receiving treatment with ipilimumab who also received palliative radiation to a single metastatic lesion exhibited rapid and substantial decrement in the size of multiple unirradiated metastatic lesions throughout her body. It is known that radiation can increase antigen presentation by certain myeloid cells (Zhang et al, 2007), suggesting that the systemic response seen in this patient resulted from an interaction of radiation and immune blockade that needs further examination. Negative regulation of T-cell activation by ipilimumab also has been tested in combination with radiation in the treatment of men with metastatic prostate cancer and appears to be safe and has evidence of enhanced efficacy (Slovin et al, 2013). Taken together, these data support an extrapolation of such concepts to the treatment of men with high-risk, nonmetastatic disease and provide a promise for enhanced local as well as distant micrometastatic disease immune surveillance.

Radio-Gene Therapy

Cytoreductive approaches to gene therapy that result in cytolytic or apoptotic cell death are generally grouped into three categories: (1) enzyme/prodrugs ("suicide gene" therapy), (2) oncolytics, and (3) cytotoxins. A rational combination of these approaches with a

more standard cytotoxic therapy such as RT may provide superior cell killing as a result of nonoverlapping modes of cell death.

Enzyme/Prodrug Gene Therapy

This method of gene therapy relies on the conversion of an inactive prodrug into a toxic drug using an enzyme vectored only to target tumor cells. In this way, active drug is limited to the transduced cells and adjacent surrounding cells. In this therapy, it is critical that the vector have high tumor cell specificity to minimize normal tissue toxicity. Prodrug-activating enzymes employed include those not normally found in humans such as cytosine deaminase, which catalyzes the conversion of nontoxic 5-fluorocytosine to cytotoxic 5-fluorouracil, and herpes simplex virus (HSV)–thymidine kinase, which assists in the conversion of ganciclovir to toxic ganciclovir triphosphate. Even when only a small percentage of cells contain the enzyme, substantial tumor reductions have been noted, given the significant cell death attributed to the bystander effect (Kim et al, 1998). A recently reported study of HSV–thymidine kinase and ganciclovir suicide gene therapy in combination with replication-competent adenovirus and radiation revealed this approach to be safe and associated with frequent negative post-treatment biopsies of the prostate (Freytag et al, 2007). To fully test this gene therapy approach, there is an ongoing multicenter randomized, double-blind control trial of an adenoviral vector that expresses the HSV–thymidine kinase gene that is delivered intraprostatically, followed by delivery of the oral antiherpetic drug valacyclovir and definitive radiation to the prostate versus placebo and definitive radiation to the prostate for men with newly diagnosed intermediate-risk prostate cancer (ClinicalTrials.gov identifier: NCT01436968). The primary end point of the trial is improvement in disease-free survival. The study will also evaluate CSS and prostate biopsy positivity 24 months after treatment. This is an exciting, contemporary investigation of this novel approach and will provide more definitive data as to the clinically relevant benefits of combined radiotherapy and gene therapeutics.

Oncolytics

Viruses alone can infect and kill tumor cells without insertion of a transgene. Certain viruses have, as part of their normal life cycle, a lytic phase that is lethal to the host cell. In the 1950s, the potential therapeutic activity of this lytic life cycle was documented when cervical cancer was treated with intratumoral injections of wild-type adenovirus with subsequent tumor responses (Smith et al, 1956). Examples of oncolytic viruses that could be used for therapy include adenovirus, vaccinia, Newcastle disease virus, HSV, influenza virus, and mumps virus. Adenoviruses are attractive vectors for gene transfer and therapy for several reasons. They have low pathogenicity for normal tissue, are not tumorigenic, and, when present, result in only mild-to-moderate clinical symptoms (Anderson, 1998). They also can effect relatively high gene transfer.

The adenovirus exerts its control over host cell growth regulation by a complex set of proteins that facilitate viral replication. Prostate-specific conditionally replicating adenoviruses can be designed by placing the genes regulating viral replication (including the early adenoviral genes, E1A) under the control of a prostate-specific promoter, resulting in a selectively replication-competent adenovirus. One potential limitation of such an approach is that E1A is known to interact with the androgen receptor in prostate cancer cells, thereby reducing the activity of both E1A and the androgen receptor and culminating in decreased viral replication and potency. Given that many patients treated with radiation are also treated with androgen-suppressive drugs, Johnson and colleagues (2013) modified the androgen receptor ligand-binding domain of the E1A–androgen receptor fusion, resulting in a virus that is activated for replication by both androgens and nonsteroidal antiandrogens. This novel virus is an ideal construct to be tested along with androgen suppression and radiation for those patients at high risk for recurrence.

The concept of combined-modality therapy, which has shown success in other tumor sites, will become more standard in prostate cancer management. The combination of gene therapy with conventional therapies such as RT and surgery provides new hope for uniform cure of patients with prostate cancer.

ACKNOWLEDGMENT

The authors of this chapter would like to acknowledge and thank Stephanie W. Lee, BS, for the expertise, time, and dedication that she contributed to the synthesis of the sections and reference listings for this chapter.

Overall Data

Follow-up after Focal Therapy

Salvage Therapy after Radiorecurrence

Conclusion

The prostate cancer pathway from screening and diagnosis through to treatment has recently been critically questioned in light of level 1 evidence pointing toward pathway-related harms that may outweigh the benefits in many men. As a consequence, guidelines on screening in prostate cancer have recommended limiting the systematic use of screening based on prostate-specific antigen (PSA) testing to avoid overdiagnosis and overtreatment. There is a clear requirement to improve the current therapeutic ratio with novel interventions. Recent interest has focused on applying magnetic resonance imaging (MRI) in men at risk, before biopsy, targeted biopsy based on MRI-derived suspicious lesions, active surveillance of low-risk disease, and tissue-preserving focal therapy in those who require treatment and have suitable disease.

Minimally invasive focal therapies in localized prostate cancer offer the potential to reduce side effects and the health care burden and costs associated with radical modalities such as surgery or radiotherapy. This chapter reviews the role of these approaches and the therapeutic dilemma that men with localized low-volume prostate cancer currently face, in the context of novel therapies that aim to find a middle ground—tissue-preserving focal therapy—that follows the paradigm of almost all other solid-organ cancers.

OVERVIEW

For most men with localized prostate cancer, there exists a challenging decision-making process. **Currently, the options often straddle two ends of a spectrum with active surveillance at one end and radical therapy, such as prostatectomy or radiotherapy, at the other.** For those men with high-risk disease, there is an absolute risk reduction in disease-specific death—of approximately 5% over 10 to 15 years—between watchful waiting (a lesser form of active surveillance that is palliative in its intention) and radical surgery, as demonstrated in the Scandinavian Prostate Cancer Group's SPCG-4 randomized controlled trial (RCT) (Bill-Axelsson et al, 2005, 2008). The more recent Prostate Cancer Intervention versus Observation Trial (PIVOT), which randomized men diagnosed in the early PSA screening era between watchful waiting and radical prostatectomy, showed no overall survival or prostate cancer-specific survival advantage over an 11-year period (Wilt et al, 2012). PIVOT did show a survival benefit for men with intermediate- and high-risk disease, and although these were subgroup analyses, they confirm the findings of SPCG-4 that treatment should be directed toward those men with clinically significant disease. However, although there is a small survival advantage for these men, it could be argued that the

morbidity from treatment (urinary incontinence, sexual dysfunction, rectal problems) questions the wholesale application of radical therapy to all men with intermediate- and high-risk disease.

The overtreatment of low-risk prostate cancer and limited effect on disease-specific mortality were further brought into context by two recent RCTs assessing the efficacy of population PSA screening. The North American Prostate, Lung, Colorectal and Ovarian (PLCO) screening trial showed no difference in prostate cancer-specific mortality between the screened and unscreened arms with a mean follow-up of 7 years. This trial was significantly flawed because there was considerable contamination (informal PSA testing) in the control arm, potentially diluting any survival advantage of PSA screening. The fourth interim analysis from the European Randomized Study of Screening for Prostate Cancer (ERSPC) showed that 781 men would need to be screened and 27 men diagnosed (and often treated) to save 1 life within a 13-year period (Schröder et al, 2014). The effect was predominantly nested in a minority of countries, suggesting heterogeneity of study conduct, delivery, health care systems, and possibly disease types based on ethnic grounds. Although arguments rage about the strengths and weaknesses of each study, what is very clear is that any advantage from screening and treatment is likely to be small if all cancers are treated uniformly. We are therefore left with a stark choice: either to abandon the screening and diagnosis of prostate cancer as recommended by many high-level health care bodies that provide guidance to governmental institutions, or to find ways to identify men who are likely to benefit from treatment, and to these men offer therapies that reduce the impact on genitourinary and rectal function if they are suitable. **Tissue-preserving strategies aim to target the cancer and not the whole organ when it is morphometrically possible to do so and thus reduce damage to collateral tissues.**

Errors in the Current Diagnostic Pathway

Men at risk of prostate cancer are those with an elevated PSA level, abnormal digital rectal examination findings, a positive family history of prostate cancer, or a specific ethnic profile. Once a risk factor has been identified, patients are advised to undergo a transrectal ultrasound (TRUS)-guided biopsy. Annually, about one million men in Europe and one million in the United States undergo a TRUS biopsy. The problem with TRUS-guided biopsy is that the operator is unable to accurately determine the location of any significant cancer. The ultrasound examination is used to identify the prostate itself and not the suspicious lesion; this results in 10 to 12 biopsy specimens being taken blindly throughout the prostate. **This is in contrast to the approach taken in most other**

Figure 117-1. The errors of transrectal biopsy. A, Misclassification of significant disease. B, Overdetection of insignificant prostate cancer. C and D, Underdetection of clinically significant prostate cancer.

solid-organ cancers, wherein the lesion is identified, usually on imaging, to direct biopsies to the area of suspicion. The random and systematic errors in diagnosis, which are inherent in TRUS-guided biopsies of the prostate, lead to a number of problems.

TRUS biopsies overdiagnose clinically insignificant prostate cancer. A man who undergoes TRUS biopsy has a 1 in 4 chance of being diagnosed with prostate cancer (Thompson et al, 2003; Bangma et al, 2007). This compares with a 6% to 8% lifetime risk of having prostate cancer that will affect a man's life. These small low-grade lesions are detected by random chance (Djavan et al, 2001) (Fig. 117-1).

TRUS-guided biopsies miss clinically significant cancers. They have an estimated false-negative rate of 30% to 45% (Djavan et al, 2001; Scattoni et al, 2007). The clinician takes 10 to 12 biopsy specimens in a manner that attempts to obtain representative tissue from the peripheral zone (see Fig. 117-1). However, this systematic error leads to several parts of the prostate not being well sampled. First, the anterior part of the gland is missed as a result of its greater distance from the rectum. Second, areas in the midline are under-sampled owing to efforts to avoid the urethra. Third, the prostate apex is often inaccessible by the transrectal route (Crawford et al, 2005; Onik et al, 2009; Barzell et al, 2012; Lecomte et al, 2012).

TRUS-guided biopsies can be unrepresentative of the true burden of cancer. The random sampling error (see Fig. 117-1) can mean that a biopsy does not hit the cancer lesion through its greatest diameter, leading to either the size or the grade of cancer or both being underestimated (Kulkarni et al, 2006). Up to half of men deemed low risk on TRUS-guided biopsies can have a higher burden or grade or both when a more accurate biopsy test is applied (Barzell and Melamed, 2007; Onik and Barzell, 2008; Taira et al, 2010). As a result of the poor risk attribution, many men and their physicians choose radical therapies from which they derive little to no survival benefit.

TRUS-guided biopsy is unstable when repeated. The pathologic status derived from TRUS-guided biopsies can be unreliable if the test is reapplied, not only at discriminating clinically significant cancer from clinically insignificant prostate cancer, but also at attributing a noncancer status versus a cancer status in about a quarter of men subjected to serial testing (Roehl et al, 2002; Porten et al, 2011; Washington et al, 2012).

TRUS-guided biopsy can cause harm. It is associated with a number of complications, the most important being urinary tract infection (1% to 8%) that can result in life-threatening sepsis (1% to 4%). Hematuria (50%), hematospermia (30%), pain or discomfort (most), dysuria (most), and urinary retention (1%) can also be expected (Abdelkhalek et al, 2012; Batura and Gopal Rao, 2013; Loeb et al, 2013b; Pepe and Aragona, 2013).

Conceptual Basis for Focal Therapy

Overtreatment becomes less of a problem if the treatment is inexpensive and is associated with low rates of toxicity. Most current treatments do not share these attributes. At present, men can expect the following rates of toxicity from radical therapies on average: 30% to 90%, erectile dysfunction; 5% to 20%, incontinence; and 5% to 20%, rectal toxicity. Indeed, men may be willing to accept higher rates of genitourinary functional preservation with lower rates of survival. This is reinforced by data from a recent discrete choice experiment showing that men are willing to consider tradeoffs between survival and side effects; for instance, on average men would wish to see 25.7 additional months of survival conferred by treatment if that treatment leads to severe urinary incontinence (King et al, 2012).

Two strategies can be used to reduce this treatment burden. First, molecular characterization and imaging modalities may be used to identify men who have high-risk cancer that requires treatment. This has yet to prove fruitful, although imaging is showing some early promise (Kurhanewicz et al, 2008; Macura, 2008; Ahmed et al, 2009a; Turkbey et al, 2009). Second, minimally invasive therapies may be used in an attempt to reduce the side effects of treatment. Although this trend has resulted in intensity-modulated radiotherapy being promoted as the preferred method of care from the radiotherapeutic perspective, on the one hand, and robotic surgery on the other, these treatments are associated with high capital and considerable recurrent costs. For instance, a recent analysis has demonstrated that there were no statistically significant differences in quality-adjusted life-years (QALYs) among the various surgical methods; surgical methods tended to be more effective than radiation, although combined external beam and brachytherapy radiation treatment for high-risk disease was the exception.

Radiotherapy techniques were consistently more expensive than surgery, although both were expensive, with costs ranging from \$19,901 (robotic-assisted prostatectomy for low-risk disease) to \$50,276 (combined radiotherapy for high-risk disease) (Cooperberg et al, 2013). Others have shown that cost savings are not realized, at least in the first year and in the United States, between open and minimally invasive surgery (Lowrance et al, 2012). Others have shown that proton beam therapy is significantly more expensive, even if it theoretically improves cancer outcomes, compared with photon beam standard radiotherapy (Konski et al, 2007). In addition, there is little robust evidence that the toxicity profile has changed (Sanghani and Mignano, 2006; Berryhill et al, 2008). One way of reducing the side effects of radical therapy may be to direct treatment to only areas of cancer, to preserve tissue and avoid damage to key structures such as neurovascular bundles, external sphincter, bladder neck, and rectum (Ahmed et al, 2007; de la Rosette et al, 2010; Eggener et al, 2010; Lindner et al, 2010b; Karavitis et al, 2011a) (Fig. 117-2).

When compared with other solid-organ malignancies, prostate cancer is an outlier. Breast, renal, thyroid, liver, and pancreatic cancers all involve tissue-preserving therapies, if appropriate, which are dependent on location and burden of cancer. It is clear that these areas of oncologic surgery developed tissue preservation, as opposed to Halsted principles for wider surgical margins, as a result of upstream diagnostic tools that are reliant on finding measurable—by palpation or imaging—disease that would undergo targeted sampling followed by targeted treatment. The transrectal biopsy has facilitated the reverse for the prostate. Random blind sampling has forced our hands as clinicians so that we have to apply radical whole-gland principles. So, if multifocality is overlooked in other organs by targeting just the measurable index lesion—the lesion that is largest and has elements of the highest grade—it is a reasonable hypothesis that targeting these lesions in prostate cancer will be sufficient in leading to acceptable cancer control rates, possibly equivalent to whole-gland therapy. In prostate cancer, a safe strategy may be to target those lesions that meet widely acceptable thresholds for clinically significant cancer. Focal therapy certainly leads to fewer genitourinary and rectal side effects, if the results of early prospective studies are found to be reproducible across populations, centers, and surgeons (Ahmed et al, 2011a, 2012d; Bahn et al, 2012).

Figure 117-2. Depiction of why whole-gland radical therapies can cause genitourinary and rectal toxicities as a result of the proximity of sensitive structures that can undergo collateral damage from surgery or radiotherapy.

To balance the unfavorable risk-benefit ratio of current standard treatments, new approaches and novel technologies are being explored. Hitherto, prostate cancer therapy has been traditionally directed toward the whole gland rather than to the area of the gland harboring cancer. It is one of the outliers in terms of cancer therapy, with most other solid-organ cancers having therapy directed toward the tumor and not primarily toward the whole organ in the majority of cases. For the prostate, a consequence of whole-gland treatment is that surrounding structures are usually damaged, with related urinary, erectile, and bowel side effects. However, new evidence has highlighted that only the index lesion—largest by volume and/or grade—drives the natural history of the disease, although prostate cancer is multifocal in most men (Ahmed, 2009). Thus a new approach delivering treatment only to the area of the gland affected by significant disease might be a reasonable approach and the best way to preserve function while retaining the benefits of cancer control. This approach has been called *focal therapy* (Ahmed et al, 2007; Eggener et al, 2010).

It follows that treatment could be patient specific. It is straightforward to envisage hemiablation of unilateral prostate cancer in which the entire lobe that is affected, regardless of volume or position of cancer, is ablated. Indeed, this is the treatment that retrospective case series of cryotherapy have delivered (see later). True focal ablation in which the tumor alone is ablated with a margin of normal tissue is also probably without contention, with the main difficulty arising from the greater precision in localization and targeting leading to potentially greater residual cancer or undertreatment rates. However, unifocal ablation is possible in only 10% to 20% of men, whereas hemiablation of unilateral disease may be possible in 30% to 40% of localized prostate cancer. Because most men have two or three lesions per prostate, a hemiablation or unifocal ablative approach would limit the patient population that could potentially benefit from focal therapy.

If tissue preservation criteria cannot be met owing to the disposition of secondary small tumors near the neurovascular bundles or sphincter muscles, it could be argued that index lesion ablation in which the largest and highest-grade tumor is ablated is warranted (Figs. 117-3 and 117-4). This could be justified to derive the benefits of lower toxicity, provided cancer control is not compromised by not treating all secondary cancer foci (Scardino, 2009). What is the justification for the inclusion of index lesion ablation? First, there is evidence that the volume of a tumor determines disease progression and that this volume equates to about 0.5 mL (Stamey et al, 1993; Epstein et al, 1994). Second, within multifocal disease is the inclusion of a large proportion of small tumors that probably

Figure 117-3. Whole-mount prostatectomy section demonstrating two lesions. On the right is the large index lesion and on the left the secondary or satellite lesion that many argue is usually clinically insignificant and does not drive the progression of the disease.

Figure 117-4. Sections taken from radical prostatectomy specimens and pathology diagram showing dominant Gleason pattern 4+3 lesion with secondary satellite Gleason pattern 3+3 prostate cancer.

represent clinically insignificant disease. Third, 80% of patients seem to have a dominant lesion, with the remaining lesions being of low grade (Gleason score 6 or lower) and a total volume of secondary lesions below 0.5 mL. Fourth, about 80% of men have a dominant tumor such as this, which also gives rise to most of the extracapsular extension (ECE). Lesions above 0.5 mL tend to yield Gleason scores of 7 or greater and are responsible for ECE if present. Foci of Gleason score less than 7 with volumes less than 0.5 mL may not contribute to disease progression over a 10- to 15-year period and therefore may not warrant treatment. Further corroborating evidence comes from elegant molecular genetic studies that point to a single lesion driving metastases and disease progression (Liu et al, 2009). It therefore seems reasonable to propose that ablation of the dominant lesion will give rise to disease control, provided the remaining lesions can be well characterized in the pretreatment evaluation. The argument has actually been taken further. There is growing traction that small, low-grade, and therefore clinically insignificant disease might be reclassified as a benign entity. Such a move, if carried out, would negate the concerns about multifocality in the vast majority of men newly diagnosed with localized prostate cancer.

PROSTATE CANCER BIOLOGY: MULTIFOCALITY AND THE INDEX LESION

If not all prostate cancer lesions are clinically significant, one might contemplate a shift from treatment directed toward the whole gland. Treatment could be directed only to cancer lesions that would cause a reduction in either quality or length of life. This represents a radical shift in how we treat the disease, but it

certainly is in tune with the paradigm shifts we have witnessed in breast, thyroid, kidney, and liver cancers, to name just a few. The concept of the index lesion therefore runs to the very core of attempts to reduce the harms of screening for and treatment of prostate cancer, because systematic biopsies that inadvertently detect indolent disease will need to be replaced by targeted precision biopsies directed at a lesion of concern.

Clinically Significant Disease and Tumor Multifocality

Tumor multifocality in solid organs is not a novel phenomenon. It is not only found in prostate cancer, but it is also well recognized at various rates of incidence in breast, thyroid, lung, and even renal cancers. In these cancers physicians have taken an approach to treat only the cancer that will cause harm, leaving small indolent tumors (often unknown of) and preserving healthy tissue. In breast cancer, lumpectomy and localized radiotherapy might now be favored over whole-breast adjuvant radiotherapy because recurrences predominantly occur in the area of surgical resection after lumpectomy (Vaidya et al, 2014). The importance of preservation of healthy thyroid tissue is well recognized by colleagues in head and neck oncology and has led to the renaming of clinically insignificant disease as *papillary microcarcinoma* (Piersanti et al, 2003). The small lung tumors found at high rates at autopsy that would have caused more harm by investigation and treatment are commonly called *pseudodisease* in recognition of their nonmalignant behavior. Such a concept is made easier because the diagnostic pathway in those malignancies involves detection of the clinical phenotype visually, with palpation, or by imaging. In other words, diagnosis and treatment are directed at measurable disease.

In stark contrast to this, prostate cancer is typically detected by a somewhat random deployment of 10 to 12 transrectal needles, and the disease is confirmed histologically via these microscopic samples. This technique was deemed adequate because the presence of disease in the prostate was all that was required to inform treatment directed at a whole-gland level. By virtue of finding many lesions through this biopsy strategy, the multifocality of the disease has been used as a rationale to treat the entire prostate. However, informed treatment decisions based on biochemical and pathologic parameters cannot be made when systematic errors in sampling of the prostate can lead to overlooking of clinically significant disease (disease that will lead to a reduction in quality or quantity of life) or undersampling, or when, conversely, clinically insignificant disease (disease that will never cause harm) is oversampled by clustering of the biopsy sites. In addition, even when disease in the prostate has been well characterized, it is sometimes difficult to predict the biologic behavior of individual cancers.

Along with multifocality, the idea that within the prostate separate cancers are behaving differently has long been recognized. In 1963 Halpert and colleagues surveyed 5000 autopsies following death from all causes (Halpert et al, 1963). In their survey they identified the presence of focal and diffuse tumors within the prostate gland. In younger men, focal tumors outnumbered diffuse tumors, but the researchers were not able to determine whether the focal tumors were precursors of diffuse tumors or if, indeed, the two types of tumors represented two forms of cancer with different biologic behavior. Thirty years after this publication, Villers and colleagues from Stanford University published their 3-mm step section analysis of 234 consecutive prostatectomies performed because of clinically detected prostate cancer from 1983 to 1989 (Villers et al, 1992). In this series a total of 500 adenocarcinomas were identified. A single cancer was found in 117 of the prostates analyzed. The remaining 117 specimens contained the clinically detectable lesion plus an additional 266 incidental tumors. Here, despite earlier studies describing diffuse tumors, the authors observed the distribution of normal tissue indicating expansion of the tumor from a single region of the gland.

Examining the Gleason grade of the dominant and secondary lesions in 100 consecutive radical prostatectomies, Karavitakis and colleagues (2011b) identified a total of 270 lesions. In the 170 satellite, secondary lesions identified, 87% were less than 0.5 mL and

99.4% had a Gleason score of 6 or less. In the 25 specimens in which two or more foci of cancer were identified, none contained the higher-grade, more aggressive disease in the secondary lesion.

Considering how size and growth of the index lesion affect outcomes in prostate cancer, Karavitis and colleagues (2012) examined the extent of positive surgical margins involving the index lesion and secondary lesions. Ninety-five consecutive whole-mount specimens from laparoscopic radical prostatectomy were examined. A total of 269 tumor foci were identified. Two of 160 (1.3%) lesions of volume less than 0.5 mL were involved in the positive surgical margin, whereas 0 of 132 lesions of volume less than 0.2 mL were involved. In the 19 cases in which multifocal cancer displayed a positive surgical margin, the index lesion was the cause in 13 cases and the index lesion plus a satellite lesion in the remaining 6 cases. In the other cases, the satellite lesion had a volume greater than 0.2 mL.

Tumor size was also found to be an important factor in PSA failure in a study by Nelson and colleagues, who analyzed 431 consecutive patients undergoing radical prostatectomy for localized prostate cancer (Nelson et al, 2006). In a multivariate analysis, tumor volume was found to be an independent predictor of PSA recurrence. The mean tumor volume for PSA recurrence was 6.8 mL.

When Wise and colleagues compared the impact of small independent cancers and the index lesion on PSA failure in 486 men treated with radical prostatectomy, they found that 83% of men had multifocal cancer within the prostate (Wise et al, 2002). Fifty-eight percent of these smaller secondary cancers were less than 0.5 mL in volume. Factors that independently predicted PSA failures were the presence of any Gleason grade 4 or 5 and the volume of the index lesion. Multiple small cancers appeared to reduce the risk of PSA failure by 14% for each additional cancer. An explanation for this is that as the index lesion increases in volume, smaller, indolent cancers are assimilated into it. There might also be a paracrine growth inhibition effect between the largest index and smaller secondary lesions, although both of these theories remain to be investigated. From these studies it starts to become clear that despite being multifocal, individual cancers within the prostate appear to express different behavior and that perhaps the most aggressive cancer is originating from a single site.

Index Lesion

There are two theories that explain multifocality of prostate cancer. One is of monoclonal expansion whereby tumors arise from the same original cell clone and multifocality is the result of intraprostatic metastasis. The other is of multiclonal expansion whereby each tumor is a separate independent lesion, genetically distinct, arising in a prostate that is predisposed to cancer through a field effect.

Specifically addressing this question, Cheng and colleagues examined the pattern of allelic loss for a tumor suppressor gene on chromosome 8p and the *BRCA1* gene on chromosome 17q in 19 patients with two or more distinct prostate tumors (Cheng et al, 1998). The pattern of allelic loss was compatible with independent tumor origin in 15 of 18 informative cases. The remaining 3 were inconclusive and could have occurred as a result of independent origin or monoclonal origin.

This raises the question: If multifocal tumors in the prostate do arise independently, do they exhibit differential behavior, and does the index lesion behave differently than the smaller secondary lesions? When one evaluates the evidence with respect to the hallmarks of malignancy, there is striking evidence demonstrating that small low-grade lesions (usually secondary) exhibit few of the traits that would qualify their status as cancer.

Reclassification of Low-Grade Low-Volume Prostate Lesions

The errors in the current pathway have been well described—namely, overdiagnosis, underdiagnosis, misclassification of risk,

and overtreatment. These errors could be overcome by a recalibration of what is classified as malignant. A recent National Institutes of Health–National Cancer Institute expert group meeting on active surveillance stated that “because of the very favorable prognosis of low-risk prostate cancer, strong consideration should be given to removing the anxiety-provoking term ‘cancer’ for this condition” (Ganz et al, 2012). Esserman and colleagues (2009) stated that “minimal risk lesions should not be called cancer,” with perhaps these lesions being called “indolent lesions of epithelial origin (IDLE).” Similar sentiments have been proclaimed elsewhere (Klotz, 2012b; Nickel and Speakman, 2012). As yet, there has been a lack of a systematic evidential approach to support such a contentious standpoint based on the current level of evidence.

The prostate is far from being an outlier. In lung cancer, there is a 1 in 6 incidence of what look to be malignant lesions histologically when autopsies are conducted. These lesions are now coined *pseudodisease* in recognition of their nonmalignant behavior (Black, 2000; MacMahon et al, 2005). In the thyroid, the autopsy incidence of indolent lesions is 1 in 2, leading to a different label of *papillary microcarcinoma* (Piersanti et al, 2003); and in the bladder, low-grade transition cell lesions have effectively been reassigned as nonmalignant by the term *papillary urothelial neoplasia of low malignant potential* (PUNLMP) (Jones and Cheng, 2006). Furthermore, another NIH consensus statement suggested that ductal carcinoma *in situ* should drop the term *carcinoma* from its terminology for the same reason (Allegra et al, 2010).

Prostate cancer is, in general, multifocal and consists of a dominant (as measured by tumor volume) focus—deemed the index lesion—and one or more separate, secondary tumor foci of smaller volume (see Figs. 117-3 and 117-4). Much bench-side and clinical evidence demonstrates that we need to rethink how we regard low-grade and low-volume lesions (Karavitis et al, 2011a). In this section, we discuss why low-Gleason pattern lesions with low volume—which in the current era are being designated as *prostate cancer*—could be regarded as nonmalignant, and perhaps called *IDLE lesions*. These lesions either have been shown to not meet the hallmarks of cancer or lack robust evidence to that effect, as opposed to the index lesion—the largest lesion with the highest grade—which seems to be primarily responsible for metastatic disease (Fig. 117-5).

The redesignation of low-volume Gleason 3+3 disease as a benign entity may represent another incremental step in the way the grading system has evolved over the years. Gleason patterns 1 and 2 are rarely assigned to prostate cancer in the current era (Egevad et al, 2012). For instance, there has been an accepted grading shift upward—the so-called Will Rogers phenomenon (Albertsen et al, 2005)—in other words, the changing definition of Gleason pattern 4 has led to the regrouping of cases previously considered Gleason 6 into the Gleason 7 category. In many cases of cancer patterns previously assigned to the lowest Gleason grade 1, recent advances in immunohistochemistry have demonstrated the presence of basal cells, identifying the cases as atypical adenomatous hyperplasia, a benign mimic of cancer (Epstein, 2000). Moreover, lesions with grades 1 and 2 have been recognized as biologically similar to grade 3, further discouraging the use of these grades. Here we discuss key evidence structured within the framework of the original six “hallmarks of cancer” famously elucidated by Hanahan and Weinberg (2000, 2011) (Fig. 117-6).

Tumor cells can generate their own growth signals and reduce their dependence on stimulation from the surrounding normal tissue microenvironment. Ross and colleagues (2011), using laser-capture microdissection, extracted neoplastic cells from radical prostatectomy specimens of 23 men with either Gleason grade 3+3=6 or 4+4=8 index lesions. mRNA expression of 18,344 unique genes was then elucidated in these extracted cells; 670 genes were discovered to be differentially expressed between Gleason sum 6 (3+3) and 8 (4+4) index lesions. The profile of upregulated genes in high-grade lesions resembled the pattern observed in embryonic, neuronal, and hematopoietic stem cells. It is important to note that endothelial growth factor (EGF) and endothelial growth factor receptor (EGFR) overexpression stimulates independent cell

Figure 117-5. The index lesion hypothesis states that one cancer cell clone leads to metastases.

Insensitivity to growth inhibitory signals

Decreased expression p27^{kip1}
Increased methylation cyclin D2

Resisting cell death

Overexpression of Bcl-2
Overexpression of DAD1

Unlimited replicative potential

Decreased androgen signaling
Overexpression of ERG

Angiogenesis

Higher MVD
Increased expression of angiogenesis factors

Local tissue invasion and Metastasis

Overexpression of CXCR4
Monoclonal nature of invasion and metastases of lesions

Mortality rates in men with only low-risk lesions

Figure 117-6. Numerous papers have demonstrated that low-volume, low-grade lesions do not demonstrate the hallmarks of malignancy as exemplified by Hanahan and Weinberg. EGFR, epidermal growth factor receptor; ERG, ETS (erythroblast transformation-specific)-related gene; MVD, microvessel density.

proliferation and cell motility through several signal transduction mechanisms including the MAPK, AKT, and RAS pathways. In addition to the upregulation of the EGFR itself in Gleason 4+4 index lesions, the group also demonstrated overexpression of *MAP2K4* and *RALA20*, the latter of which is a migration-promoting gene activated by EGF. Also, the downregulation of *RESP2* (which inhibits EGFR actions by resulting in the endocytosis of the receptor) was established. The investigators also noted that two genes that inactivate phosphor-AKT—*PHLPP* and *PML*—were downregulated in Gleason 4+4 cancer.

Cancer cells must be able to resist the normal antigrowth signals that push them into a quiescent phase of the cell cycle or enter into postmitotic phases that ensure specific cell differentiation. The D-type cyclins are involved in the regulation of transition from G₁ to S phases during the cell cycle. It has been reported that cyclin D2 is a direct target of Myc and that accumulation of cyclin D2 promotes the sequestration of p27, which is a cell cycle inhibitor, and this subsequently results in entry to the cell cycle. Inactivation of cyclin D2 may be a result of aberrant promoter hypermethylation. Using 101 radical prostatectomy specimens, [Padar and colleagues \(2003\)](#) reported that maximum Gleason pattern 3 tumors had significantly greater methylation frequency of cyclin D2 in comparison with those containing Gleason patterns 4 or 5. Transforming growth factor- β (TGF- β) can impede growth by the induction of inhibitors of cyclin-CDK complexes including p27^{kip1}. Using radical prostatectomy specimens, [Guo and colleagues \(1997\)](#) showed that there was progressively diminished p27^{kip1} immunostaining with increasing Gleason score in prostate neoplasms. All Gleason pattern 5 foci were totally negative for p27^{kip1} staining, suggesting that these cells are unresponsive to the growth-inhibitory effect of TGF- β . This loss of p27^{kip1} was associated with an increase in the proliferative index of the higher-grade prostate cancers.

The ability of cancer cells to resist programmed cell death (apoptosis) is key to ensuring continued growth and proliferation. [True and colleagues \(2006\)](#) used laser capture microdissection to acquire specific subpopulations of prostate cancer cells consistent with lesions containing Gleason patterns 3, 4, and 5 from 29 radical prostatectomy specimens. The group profiled transcript abundance levels using cDNA microarray analysis and developed an 86-gene model capable of differentiating between lesions containing Gleason pattern 3 from higher-grade patterns 4 and 5. This model was observed to be 76% accurate in characterizing an independent set of 30 primary prostate tumors. One specific discriminatory gene identified was *DAD1*, a gene encoding defender against death, which is a downstream target of the nuclear factor- κ B (NF- κ B) survival pathway and displays an antiapoptotic function. *DAD1* protein expression was subsequently elucidated by immunohistochemistry in tissue microarrays comprising formalin-fixed radical prostatectomy cores that, together, contained 131 benign and 306 cancerous samples. *DAD1* protein levels demonstrated a strong correlation with Gleason grade, with tumors of patterns 4 and 5 more likely to stain intensely compared with Gleason pattern 3. Another more familiar antiapoptotic gene is *BCL2*. Its role in carcinogenesis and development of castrate resistance in prostate cancer has been well established. Recently, [Fleischmann and colleagues \(2012\)](#) performed immunohistochemical analysis on a tissue microarray of 3261 radical prostatectomy specimens. *BCL2* expression was significantly upregulated in those lesions with a high Gleason score—that is, those lesions that included Gleason patterns 4 and 5 in contrast to those that were only pattern 3.

Mammalian cells appear to have an inherent autonomous function, independent of cell-to-cell signaling, which limits their replicative ability. Cancers disrupt this intrinsic pathway. [Tomlins and colleagues \(2007\)](#) used laser-capture microdissection to obtain 101 specific cell populations from 44 men and then separated the samples into two groups: low-grade, only Gleason pattern 3, and high-grade samples with Gleason pattern 4 or higher. The investigators identified significantly decreased androgen signaling in high-Gleason grade lesions, similar to metastatic prostate cancer, which may reflect dedifferentiation and explain the clinical association of

grade of the index lesion with prognosis. [Hendriksen and colleagues \(2006\)](#) also reported lower androgen signaling in high-Gleason pattern prostate cancer compared with low-Gleason pattern lesions. They suggested that localized prostate cancer cells become more aggressive by selectively downregulating androgen-responsive genes, resulting in increased tumor cell replication and proliferation, dedifferentiation, or reduced apoptosis. *TMPRSS2-ERG* translocations are the most prevalent genetic alterations in prostate cancer. This gene fusion results in overexpression of the ERG transcription factor. Although the association between ERG gene rearrangements and aggressive prostate cancer is controversial, it is becoming apparent that it plays a significant role in disease progression. Because *TMPRSS2-ERG* fusions lead to frequent alterations (460%) of the ERG proto-oncogene in early-stage prostate cancer, their evaluation in preneoplastic cells as well as multifocal lesions from the same patient has potential to define its role in prostate cancer onset, progression, and heterogeneity. In fact, evidence suggests that ERG protein expression can be used as a surrogate marker for ERG genomic rearrangements. One group established that ERG protein expression was statistically significantly higher in tumors with larger volumes and higher Gleason grade from radical prostatectomy specimens, presumably as a result of this transcription factor promoting tumor growth and proliferation ([Bismar et al, 2012](#)). Another group showed that *TMPRSS2-ERG* gene fusions predominantly resided in the index lesion but were also present in some secondary lesions as well as some histologically benign areas of prostate ([Furusato et al, 2008](#)). Other scientists have shown a strong relationship of expression of *TMPRSS2-ERG* fusion mRNA isoforms with pathologic measures of clinical outcome (seminal vesicle invasion, ECE) in lesions from radical prostatectomy specimens ([Wang et al, 2006](#)). They found expression of the fusion in benign glands of the prostate. This underlies the uncertainty of this particular gene fusion's role in prostate cancer development and progression.

Neovascularization is a normal physiologic process that takes place during embryonic development and wound healing. The process is also required for solid tumors to grow beyond 1 mm in diameter and for their subsequent rapid growth ([Folkman, 1995](#)). Malignant prostate cells secrete angiogenic molecules such as vascular endothelial growth factor (VEGF), fibroblast growth factor-2, TGF- β , and cyclooxygenase-2. Raised levels of VEGF and increased microvessel density (MVD) are related to a poorer prognosis in prostate cancer ([West et al, 2001](#); [van Moorselaar et al, 2002](#)). Several observations suggest that higher-grade and larger-volume lesions are associated with increased angiogenesis. For example, there is a strong correlation between elevated MVD and higher Gleason score ([Brawer et al, 1994](#); [Erbersdobler et al, 2010](#)). In addition, [Mucci and colleagues \(2009\)](#) established that poorly differentiated tumors demonstrated greater MVD and irregularity of the blood vessel lumen with smaller vessels. In this study, during a 20-year follow-up period, bone metastases or cancer-related death occurred in 44 of 572 men. Lethal prostate cancer was 6 times more likely to occur in neoplasms exhibiting the smallest vessel diameter (based on quartiles). Also, cancers with the most irregularly shaped vessels were 17 times more likely to result in mortality. MVD was not linked to cancer-specific mortality after adjusting for clinical factors.

Cancers must exhibit the ability to invade local tissues and spread beyond the tissue and organ of origin. Evidence exists pointing to the lack of invasive and metastatic behavior of most prostate cancer lesions. For instance, when individual prostate cancer lesions, derived from one patient's primary prostate cancer specimen, were implanted into a murine model, only one lesion showed characteristics of local invasion and eventually formed metastases ([Lin et al, 2010](#)). CXCR4, a chemokine receptor, has been found to be upregulated in localized high-grade Gleason 4+4 index lesions in comparison with Gleason 3+3 index lesions. This G protein-coupled transmembrane receptor plays a key role in the directional migration of cancer cells to specific metastatic sites in response to its ligand CXCL12. The CXCR4 receptor has been associated with the establishment of lymph node and bone metastasis in

prostate cancer, possibly through activation of the RAS oncogene family member *RAP1A*, which has also been found to be upregulated in Gleason pattern 4 index tumor lesions relative to those containing solely a Gleason pattern 3. In addition, studies have suggested that hypoxia induces CXCR4 expression in tumor cells via hypoxia-inducible factor-1 α (HIF-1 α) (Schioppa et al, 2003; Staller et al, 2003). Larger-volume tumors, specifically the index lesion in prostate cancer, are significantly more likely to have central hypoxic areas. This results in the expression of the CXCR4 receptor on the tumor cell membrane, allowing the cancer cells to migrate or metastasize away from the area of low oxygen tension, down a CXCL12 concentration gradient, to areas of high oxygen concentration. The ligand CXCL12 is secreted at particularly high levels by lymph node and bone marrow stromal cells.

Investigators from Stanford (Stamey et al, 1999; Wise et al, 2002) have reported that percentage of Gleason pattern 4 and 5, cancer volume of the largest tumor, positive lymph node findings, and intraprostatic vascular invasion were independently associated with prostate cancer progression. Another group observed that 80% of secondary foci are less than 0.5 mL and have the same volume distribution as tumors found incidentally in patients who undergo cystoprostatectomy for bladder cancer (Nevoux et al, 2012). It has been proposed that tumor volume is associated with PSA recurrence (Nelson et al, 2006) and that prostate lesions smaller than 0.5 mL are clinically insignificant owing to the long doubling time of this cancer to result in metastases (Stamey et al, 1993). Schmid and colleagues observed that 79% of men with previously untreated prostate cancer of all clinical stages who underwent serial PSA measurements during a period of at least 12 months had a tumor-doubling time greater than 24 months (Schmid et al, 1993). Primary tumor volumes that theoretically lead to distant metastases tend to be at least 4 mL (McNeal et al, 1990). In that case, with an estimated tumor volume doubling time of 2 years, it would take about 12 years for a 0.5-mL lesion reach a volume of 4 mL. There also seems to be a strong correlation between pathologic and staging parameters of poor prognosis (extracapsular invasion, seminal vesicle invasion, metastases) with individual cancer lesion volume. Lesions measuring 0.5 mL had a 10% incidence of capsular invasion, whereas lesions measuring 4.0 mL had a 10% probability of seminal vesicle invasion. Lesions measuring 5.0 mL had a 10% incidence of metastases (Bostwick et al, 1993). There is a low incidence of Gleason pattern 4 or greater in secondary nonindex lesions, and very rarely are pathologic features such as seminal vesicle invasion or ECE found in secondary lesions (Bott et al, 2010; Karavitis et al, 2011b). Furthermore, there seems to be a correlation between index lesion volume and biochemical progression-free survival (Rashid et al, 1999; Fuchsjäger et al, 2010). Therefore the evidence certainly points to the index tumor as the one with malignant potential, rather than all lesions (Haggman et al, 1997).

A word of caution is, however, necessary. One group observed that one in four lesions that invaded the capsule were not the index lesion (Ruijter et al, 1996), and other scientists showed that tumors that locally invade are not necessarily large (Miller and Cygan 1994). In fact, circulating tumor cells and occasionally lymph node metastases have been found in men who have small lesions (0.2 mL) (Gburek et al, 1997; Schmidt et al, 2006). In a series of 239 patients with tumor volume less than 0.5 mL, investigators (Kikuchi et al, 2004) demonstrated that 43 cases were poorly differentiated, 11 had ECE, 6 had positive surgical margins, and 2 had positive lymph nodes, and 7 patients experienced progression within 5 years. Greene and colleagues (1994) assessed DNA ploidy status, which is an independent prognostic factor for localized prostate cancer. Of 141 separate cancers in 68 patients, the group discerned that 15% of those 0.01 to 0.1 mL and 31% of those 0.11 to 1.0 mL in volume were nondiploid. Thus, tumor volume in itself did not adequately describe the biologic potential of prostate cancer on its own and should be combined with other factors, predominantly Gleason grade (Andreoiu et al, 2010).

One paper that does counter this argument is from Haffner and colleagues (2013). In this study, whole genome sequencing was used to characterize the lethal cell clone in a single patient who

died of metastatic prostate cancer. It is interesting to note that the analysis revealed that the lethal clone arose from a small, low-grade cancer focus in the primary tumor. However, this study has a number of problems. First, the patient was treated with multiple therapies that might have altered the metastases that eventually were sequenced. Second, the Gleason 6 area supposedly causing metastases was within a larger tumor that covered almost the entire prostate. This Gleason 6 area would in no way be equivalent to a solitary 0.1-mL or 0.2-mL Gleason 6 lesion. Barbieri and colleagues (2014) have argued that the lethal subclone is unlikely to have originated as a small, low-grade lesion because several areas within the prostate showed the same types of mutation, making these very likely to be the same tumor. They state that the lethal area likely began as a relatively large, *SPOP*-mutant tumor displaying significant amounts of Gleason pattern 4 with a small area acquiring mutations in tumor suppressors *TP53* and *PTEN*, driving the metastatic phenotype. Lastly, even if it is true that this area caused a metastasis, it is likely a rare occurrence because otherwise the one third of the male population with small cancer lesions in the prostate would need to undergo radical therapies.

Although many have focused on this one case report, a number of other studies have demonstrated that metastases occur almost always from the index lesion. Further, Ross and colleagues (2012) have shown that pure Gleason 6 disease almost never metastasizes. This study evaluated radical prostatectomy databases at four academic centers for cases of Gleason score of 6 or lower with only those prostatectomies submitted and embedded in their entirety with pelvic lymph node dissections. Of 14,123 cases, 22 had positive nodes, although histopathologic review of 19 cases (3 cases were unavailable) showed higher grade than originally reported. In other words, no case of pure Gleason 6 on prostatectomy specimens demonstrated metastases to lymph nodes.

The molecular correlation of individual lesions with lymph node metastases has added further strength to the argument that, despite multifocality, prostate cancer disease progression is likely to be related to lesions that meet certain minimal grade and volume thresholds. *TMPRSS-ERG* gene fusions observed in lymph node metastases are shared with the index lesion and not small satellite low-grade lesions (Guo et al, 2012) or secondary high-grade and high-volume lesions (Perner et al, 2010). It is important to note that researchers have elucidated that metastatic deposits share one common cell of origin (Ahmed, 2009; Liu et al, 2009), although the question of whether the metastatic clone originated from the index lesion is something that was impossible to address in this case series owing to the nature of men from whom the tissue samples were taken.

Postmortem studies have confirmed a one in three incidence of so-called prostate cancer in men who died of other causes. Similar rates are seen on assessing the prostates taken from cystoprostatectomy specimens when men underwent surgery for high-risk or invasive bladder cancer (Nevoux et al, 2012). Therefore, because one third of men have prostate cancer that will not affect them within their lifetime, it is not surprising that small low-grade lesions have low (possibly absent) malignant potential (Sakr et al, 1996). In addition, such epidemiologic facts support the assertion that most prostatic lesions, especially those of low volume and low Gleason grade, currently called cancer do not demonstrate tissue invasion and eventual metastases.

Two groups have underlined the low malignant potential of Gleason grade 6 disease. Eggener and colleagues (2011) demonstrated that of 9775 men who had only Gleason 6 low-risk disease in radical whole-mount prostatectomy specimens, only 3 died of prostate cancer in a 15-year period. In fact, on review, 1 of these cases had a small amount of Gleason pattern 4 within it; the other 2 were not available for review. This finding cannot simply be accounted for by the success of surgery itself. Other groups have shown similar findings with biochemical recurrence (a surrogate outcome) in smaller cohorts of men (Miyamoto et al, 2009; Lee et al, 2011).

Clinical experience with active surveillance now suggests there is an estimated risk of metastasis of less than 1% at 2 to 8 years

(Dahabreh et al, 2012) and disease-specific mortality of 1% at 8 years while on surveillance (Klotz, 2012a) for men with low-risk disease as classified by a diagnostic TRUS-guided biopsy. The Toronto active surveillance series showed that all prostate cancer-related mortality occurred in men who had been reclassified as higher risk and who were offered radical treatment (Klotz et al, 2010). However, only one patient in this series who was treated after a relatively prolonged period of observation subsequently experienced progression to metastatic disease and death. Therefore, it is likely that reclassification of disease risk and subsequent radical treatment reflect undersampling of the prostate rather than true progression. Two recent reports from active surveillance cohorts from three regions that participated in the ERSPC study add a further shade of uncertainty for intermediate-risk disease. The first from Rotterdam and Helsinki looked at 509 men; 381 were low risk and 128 intermediate risk (Bul et al, 2012). During a median 7.4 years of follow-up, 221 men (43.4%) switched to deferred treatment, with 152 (39.9%) in the low-risk group undergoing treatment and 69 (53.9%) of the intermediate-risk group. Distant metastases were found in 1 low-risk and 3 intermediate-risk men. The Göteborg arm looked at 439 (45.4%) men managed with surveillance from a total of 968 in the screening group (Godtman et al, 2013); 224 (51.0%) were very low risk, 117 (26.7%) low risk, 92 (21.0%) intermediate risk, and 6 (1.4%) high risk. Two hundred and seventy-seven men continued on surveillance, of whom 133 (59%), 58 (50%), 46 (50%), and 3 (50%) were still on surveillance at study end in each group, respectively. Sixty men died during follow-up; only 1 man (intermediate risk) died from prostate cancer 12.7 years after diagnosis after having developed distant metastases at 8.6 years. However, despite a significant body of evidence demonstrating that this is a safe approach (Dahabreh et al, 2012), active surveillance seems to be infrequently offered to or chosen by men, with only 1 in 10 in the United States and 4 in 10 in the United Kingdom with low-risk disease undergoing active surveillance (Cooperberg et al, 2004; McVey et al, 2010). This may be physician or patient related but likely is a combination of both. With the uncertainty around longer follow-up, especially in the intermediate-risk group, this is hardly surprising, but it does point to the need for improved therapeutic interventions that can minimize the harms of treatment if that is what men and their physicians choose.

IDENTIFYING THE PATIENT POPULATION FOR FOCAL THERAPY

Any man with localized prostate cancer suitable for curative therapy should be regarded as suitable for some form of focal therapeutic intervention. Such a pragmatic approach would not limit the age to a lower or an upper boundary. However, focal therapy has been seen by many, predominantly in the United States, as an alternative to active surveillance, whereas others, predominantly in Europe, have argued that focal therapy should also be regarded as an alternative to radical therapies (Ahmed and Emberton, 2008).

The arguments for focal therapy to be carried out only in men suitable for active surveillance are (1) reduction of the potential psychological morbidity associated with men not having treatment for a cancer—that is, for patients, “some form of treatment is better than none,” and (2) reduction of the surveillance of cancer progression rate (about one third require delayed intervention within 5 years). Although up to 10% of men on active surveillance choose to have intervention within 5 years despite the absence of biochemical or histologic progression, questionnaire surveys have shown conflicting findings about the level of anxiety present in such cohorts. Furthermore, despite the progression rate, the mortality rate has been negligible, so it can be argued that most men can avoid treatment and those who have delayed intervention have a period of time free of treatment-related side effects. However, the period of low side effects could be extended if focal therapy were to be carried out at diagnosis or, indeed, at the time of disease progression after a period of surveillance. The argument against

men who are suitable for active surveillance undergoing focal therapy is that any treatment within this group is liable to be over-treatment. Any treatment, regardless of the encouraging functional outcomes that it may demonstrate, will carry greater morbidity than a management strategy in which two thirds of men with low-risk disease can avoid side effects of treatment and the others can delay such morbidity. Nonetheless, active surveillance is not without harm and burden, with surveillance blood tests and biopsies performed every 1 to 2 years (with their concomitant risk of complications), although the specific evidence with regard to repeat biopsy in active surveillance is conflicting (Fujita et al, 2009; Bergman et al, 2012; Hilton et al, 2012; Loeb et al, 2013a).

It can be argued that the emergence of focal therapy as a strategy to reduce the side effects of conventional whole-gland therapies requires us to evaluate its potential within men who, as a result of harboring intermediate- to high-risk localized disease, would undergo radical therapies (Figs. 117-7 to 117-10). Despite the higher-risk disease status, evidence suggests that the oncologic benefits of radical therapies would be seen only after 10 years. A strategy that treats the cancer and carefully monitors untreated tissue for de novo cancer may obviate the need for any further radical therapies in the future or delay it for a number of years, during which the man is free of treatment-related side effects. The problem with such a proposal is the risk of progression to metastases in intermediate- to high-risk disease. Any undertreatment of cancer foci resulting from poor localization of the tumor may allow a window of opportunity in which local curative treatment may not be successful. The prolonged natural history of prostate cancer, even in these groups, precludes such an argument.

Figure 117-7. Schematic of a gland that would not be suitable for focal therapy owing to multifocal clinically significant prostate cancer lesions.

Figure 117-8. Unifocal lesion suitable for focal ablation.

TABLE 117-1 Definitions Commonly Used to Define Clinically Significant Prostate Cancer

DEFINITION	GLEASON GRADE	MAXIMUM CANCER CORE LENGTH	TEST IN WHICH TO USE
Epstein et al, 1994	≥3+4	≥3 mm	TRUS biopsy
Stamey et al, 1993	≥3+3	≥3 mm	TRUS biopsy
Harnden et al, 2008	≥3+4	≥3 mm	TRUS biopsy
Goto et al, 1996	≥3+4	≥2 mm	TRUS biopsy
Ahmed et al, 2011b (UCL Definition 2)	≥3+4	≥4 mm	Transperineal template or image-targeted biopsy
Ahmed et al, 2011b (UCL Definition 1)	≥4+3	≥6 mm	Transperineal template or image-targeted biopsy

Figure 117-10. Multifocal prostate cancer but biologically unifocal—potentially suitable for index lesion ablation.

Localization of Disease

Focal therapy requires accurate localization of disease to drive precision ablation. Localization of disease requires histology and imaging, either alone or in combination, and therefore represents an additional health care burden that forms part of focal therapy intervention. An accurate localization strategy will more clearly define the patient population in terms of stage, grade, and disease burden.

Before discussing the performance characteristics of different biopsy strategies, it is important to define what level or threshold of disease we are expecting biopsy strategies to find. A number of definitions of significant disease have been published (Table 117-1). The Epstein, Stamey, Harnden, Goto, and Ahmed/University College

London (UCL) definitions all vary and have been validated using different reference standards—that is, TRUS, radical prostatectomy, or transperineal prostate mapping (TPM) (Stamey et al, 1993; Epstein et al, 1994; Goto et al, 1996; Harnden et al, 2008; Ahmed et al, 2011b). Overall, however, it seems that most studies have a widely used definition of clinically significant prostate cancer of 0.5 mL or greater in volume and/or Gleason grade 3+4 or higher. Several studies report on the detection rates of any cancer between biopsy strategies as opposed to the detection rate of clinically significant and clinically insignificant cancer.

A definition for clinically significant disease that has been validated using an accurate sampling strategy (either TPM or radical prostatectomy) must be agreed on. Biopsy strategies can then be compared using this definition to determine the most accurate method able to guide focal targeted therapy. It is likely that definitions will vary according to the patient’s baseline characteristics and other risk factors.

Biopsy

When considering focal therapy, the role of prostate biopsy is not only in cancer diagnosis but also in characterization and localization of individual lesions (Ho et al, 2011). Biopsy strategies have evolved considerably to accurately identify, characterize, and localize lesions while trying to minimize risks to patients and reduce overall costs. Some of these strategies include taking biopsies via different anatomic approaches (transrectal, transperineal), as well as increasing the number of cores taken (saturation, mapping) and decreasing the number of cores but improving their deployment into the gland (targeted).

Systematic Transrectal Ultrasound–Guided Biopsy

Currently, systematic TRUS-guided biopsy is still the standard of care (Heidenreich et al, 2014a). However, several studies have reported on the limitations of TRUS biopsy that hinder its ability to guide focal therapy. First, TRUS biopsy may miss up to 30% of clinically significant prostate cancer. Anterior regions of the prostate are frequently overlooked by TRUS biopsy, and it has been estimated that this is where approximately 30% of cancers reside (Bouye et al, 2009). Repeated TRUS biopsies do not seem to improve cancer detection rates. Studies have shown that detection rates on first, second, third, and fourth biopsies have been reported to be 14% to 22%, 10% to 15%, 5% to 10%, and 4%, respectively (Lujan et al, 2004; Djavan et al, 2005; Anastasiadis et al, 2006). Repeating TRUS biopsies because of negative results and a rising PSA level places men at increased risk of sepsis as well as causing anxiety from the uncertainty and delayed diagnosis. Second, TRUS biopsies are taken in a random manner and therefore cannot accurately localize individual areas of disease. Mayes and colleagues found that sextant TRUS biopsy has a low positive predictive value of 28%, with a high false-positive rate of 72% for detecting unilateral disease (Mayes et al, 2011). Washington and colleagues (2012) showed that although TRUS biopsy could identify lesions on the same lobe as the dominant lesion 81% of the time (95% confidence

interval [CI] 0.7 to 0.9), in only 22% was the correct location identified. The median number of cores per biopsy increased with successive biopsies: 14 cores for the first biopsy, 16 for the second round, and 17 for the third round. Because the patient is often in the left lateral position for TRUS biopsy, subsequent targeted treatment is somewhat difficult because there are no proper landmarks to clearly identify specific locations. Third, it is difficult to interpret whether the tumor is of small volume (and potentially insignificant on histology) or of large volume or high Gleason score (and potentially pathologically advanced) (Andriole et al, 2007). Indeed, when compared with the gold standard prostatectomy specimens, TRUS biopsy has been shown to understage or undergrade disease in up to 30% of cases (Epstein et al, 2005; Chun et al, 2010). Last, some of the additional harms of TRUS biopsy include rectal bleeding and potentially life-threatening postbiopsy sepsis.

Saturation Biopsy

Prostate saturation biopsy was initially introduced by Borboroglu and colleagues (2000) and consisted of taking at least 20 biopsy cores. Studies conflict in showing whether saturation biopsies provide more accurate disease diagnosis.

Transrectal Saturation Biopsy

De la Taille et al (2003) compared the cancer detection rates of taking 6, 12, 18, and 21 systematic TRUS biopsy samples. Overall, cancer detection rates for these groups were 22.7%, 28.3%, 30.7%, and 31.3% respectively. The 21-sample procedure statistically improved the cancer detection rate by 37.9% relative to the 6-sample procedure. There was no comment on the detection rate of clinically significant cancer detection rates in this study.

Epstein and coworkers (2005) performed saturation biopsy on consecutive radical prostatectomy samples. Using Epstein's criteria of insignificant tumor less than 0.5 mL, organ confined, seminal vesicles and lymph nodes negative for tumor, and no Gleason pattern 4 or 5, 71% of the cancers at radical prostatectomy were classified as insignificant, and 29% had been misclassified using standard biopsy schemes. The false-negative rate of saturation biopsy for clinically significant cancer was also reported as 11.5% with sensitivity and specificity of 71.9% and 95.8%, respectively.

Li and colleagues (2014) retrospectively compared 3338 men with a 12- to 14-core biopsy scheme (extended biopsy) with 438 men with a 20-core biopsy scheme (saturation biopsy). A higher rate of low-grade prostate cancer as defined by Gleason score below 6 was detected in the saturation biopsy group compared with the extended biopsy group (50.0% vs. 41.4%; $P = .015$). However, using Epstein's criteria for clinically insignificant disease, the saturation biopsy group did not detect a higher rate of clinically insignificant prostate cancer compared with the extended biopsy group (21.2% vs. 17.9%; $P = .223$).

Irani and colleagues (2013) performed an RCT comparing 12- versus 20-core TRUS biopsy. Patients were biopsy naive and had PSA levels less than 20 ng/mL and no nodule on digital rectal examination. No significant difference was found between the groups for cancer detection rate or for Gleason score, tumor length, and proportion of cancer affecting both lobes. Using D'Amico criteria for low-risk cancer (Gleason 6 and PSA level less than 10 ng/mL and T1c or T2a clinical stage), there was no significant increase in low-risk cancers detected in the 20-core biopsy group compared with the 12-core biopsy group (47% vs. 39%; $P = .32$).

Transperineal Saturation Biopsy

Novara et al (2010) examined 143 men with previous negative TRUS biopsy who underwent a 24-core freehand transperineal saturation biopsy; 26% of patients were found to have cancer. The majority of these (65%) had Gleason grade 6 disease, and only 1 patient had Gleason grade 8 disease. Twenty-one of 37 patients with cancer had radical prostatectomy; 8 of these were found to have pathologically locally advanced disease (pT3ab N0 cancers) and 4

to have ECE. It was not made clear whether this correlated with biopsy outcome. Eight of the 17 patients with a Gleason grade 6 on biopsy were found to have Gleason grade 7 on radical prostatectomy review.

Transperineal Saturation versus Transrectal Ultrasound Saturation Biopsy

Abdollah and colleagues (2011) matched 280 patients who underwent either TRUS or transperineal saturation biopsy taking 24 cores. Overall, the prostate cancer detection rate was 28.6%. There was no statistically significant difference in prostate cancer detection rate between the two approaches (31.4% TRUS vs. 25.7% transperineal). Complications of saturation biopsy are similar to those of TRUS and include hematuria, hemospermia, perineal hematoma, urinary tract infections (UTIs), acute urinary retention, and prostatitis.

Transperineal Template Prostate Mapping Biopsy

For transperineal template prostate mapping biopsy, the patient is placed in the lithotomy position with a brachytherapy grid against the perineum to guide the procedure. This has several advantages over the problems associated with TRUS biopsy (Fig. 117-11).

Firstly, the brachytherapy grid has 5-mm holes, allowing for systematic sampling of the entire prostate. This can ensure comprehensive coverage of the prostate and can sample areas commonly missed by TRUS biopsy (apex, anterior horn of peripheral zone, transition zone). Crawford and colleagues (2013) performed a computer-simulated study on 40 autopsy prostate specimens. The simulation used TPM with either 5-mm or 10-mm sampling. Overall, 5-mm sampling identified more cancers than 10-mm sampling (76% vs. 45%, respectively) and also detected tumors with a higher Gleason grade 4/5 (77% vs. 40%).

Systematic sampling provides a more precise, three-dimensional (3D) representation of location, volume, and extent of the disease (Barzell and Melamed, 2007; Onik et al, 2009). Studies have also reported the upstaging and upgrading of disease on TPM after previous TRUS biopsy. One study has shown that TPM upstaged in almost half (45.6%) of cases, and one third to one half (27.2% to 46%) of cases were upgraded (Barqawi et al, 2011) (Fig. 117-12).

Because the TPM biopsy is performed with the patient in the lithotomy position, this will often be the same position used for subsequent focal therapy. This aids subsequent treatment planning, as a fixed set of reproducible coordinates can allow targeted treatment.

Transperineal Prostate Mapping Biopsy versus Transrectal Ultrasound Biopsy

Lecornet and colleagues (2012) also performed computer simulation studies comparing standard TRUS biopsy, optimized TRUS biopsy, and TPM in the detection of clinically significant cancer using two definitions: (1) Gleason score of 7 or higher and/or lesion volume of 0.5 mL or more, and (2) Gleason score of 7 or higher and/or lesion volume of 0.2 mL or more (Ahmed et al, 2011b). Random localization error (RLE) to simulate errors introduced by imperfect needle placement, for example because of human error and needle deflection, was also incorporated into the analysis. The area under the curve (AUC) to detect and rule out definition 1 cancer was 0.69, 0.75, 0.82, and 0.91 for standard TRUS with RLE 15 mm, standard TRUS with RLE 10 mm, optimized TRUS, and TPM, respectively. For definition 2 cancer, the AUC was 0.67, 0.74, 0.81, and 0.91, respectively (see Figs. 117-4 and 117-5). The difference in AUC between the different biopsy strategies was greater for anterior lesions. Standard TRUS missed 47% of lesions 0.5 mL or greater and 79% of those 0.2 mL to 0.5 mL. Another similar simulation study performed by the same group showed that the accuracy

Figure 117-11. Diagram demonstrating how transperineal template-guided biopsies are carried out. If the sagittal length of the prostate is longer than the throw of the biopsy needle, then two biopsy specimens are taken from the same coordinate. U/S, ultrasound.

of TPM vs. standard TRUS (RLE 15 mm) was 0.91 versus 0.70, respectively, for lesions 0.2 mL or larger and 0.5 mL or larger (Hu et al, 2012).

Barzell and Melamed (2007) reported on 80 patients previously diagnosed with prostate cancer on TRUS biopsy who were considering focal cryotherapy and who were rebiopsied with TPM biopsy and repeat TRUS biopsy. Patients were deemed suitable for focal cryoablation if only unilateral cancer was found after repeat TRUS and TPM. TPM biopsies detected 36 of 36 (100%) unsuitable candidates; repeat TRUS biopsies picked up only 5 of 36 (14%). Sixty-one of 66 (92%) were considered suitable for focal cryoablation by repeat TRUS findings; however, only 30 of 66 (45%) were deemed suitable by TPM findings. Thus, repeat TRUS-guided biopsies had a false-negative rate of 47% (31 of 66) in excluding patients from focal cryoablation. The template map was reported as crucial in providing cryotherapy treatment to eligible men. It permitted selective targeted ablation of the areas of cancer while sparing uninvolved parts of the prostate. Recently, our own group has shown that in 291 men who underwent TPM biopsies and had previously undergone TRUS biopsy, about 90% were suitable for focal therapy if this included index lesion ablation (Singh et al, 2014).

Reported drawbacks of TPM, however, include the laborious process in terms of setup, anesthesia requirement, and greater histopathology processing time as a result of the increased number of samples, with the consequent costs. Complications of TPM include urine retention (5% to 10%), hematuria (2%), and temporary erectile dysfunction, although rates of sepsis are very low (<0.5%) (Hara et al, 2008; Merrick et al, 2008).

Imaging: Advances in Ultrasound

Increased vascularity or changes in blood flow are an important feature of prostate cancer and have been associated with higher Gleason grades (Wilson et al, 2004; Heijmink et al, 2006). These features have driven improvements in diagnostic imaging. In terms of TRUS, color Doppler imaging measures blood flow velocity and direction. Contrast-enhanced transrectal ultrasonography (CE-TRUS) involves detecting the difference in acoustic impedance between the contrast agent and adjacent tissue (Jakobsen et al, 2001). Elastography demonstrates the higher cell and vessel density in prostate cancer based on increased stiffness in comparison to the surrounding normal tissue (Aigner et al, 2012). Prostate HistoScan-

ning (PHS) works by extracting and quantifying statistical features from back-scattered ultrasound data to detect specific changes in tissue morphology and therefore distinguish between benign and cancerous tissue (De Coninck et al, 2013).

It was previously thought that hypoechoic nodules on ultrasound were caused by increased MVD. However, up to 30% of all prostate cancers are isoechoic, and it is estimated that a hypoechoic nodule has a 17% to 57% chance of being identified as prostate cancer (Frauscher et al, 2003). Artifacts can be caused by visceral motion or patient or probe movement that interrupts stable blood flow. There have been various studies comparing the aforementioned ultrasound techniques and their accuracy in diagnosing prostate cancer.

Zhao and colleagues (2013) compared TRUS with CE-TRUS in 65 patients. Targeted biopsy to abnormal CE-TRUS (CE-TRUS TB) areas were compared with systematic 12-core biopsy. The cancer detection rate of CE-TRUS targeted biopsies was significantly higher than systematic biopsies (75% vs. 48.2%, respectively). The sensitivity, specificity, and accuracy of CE-TRUS were also higher than those of TRUS (79.3%, 86.1%, and 83.1% vs. 65.5%, 69.4%, and 67.7%). Benign prostatic hyperplasia and acute and chronic prostatitis were reported to be important causes of false-positive results.

Brock and colleagues (2012) compared gray-scale ultrasound (GSU) and real-time elastography (RTE) in 353 patients. Overall, cancer was detected in 45.3% of patients. Detection rates for RTE and GSU were 51.1% and 39.4%, respectively. RTE had better sensitivity than GSU (60.8% vs. 15%); however, GSU had better specificity (68.4% vs. 92.3%). The negative predictive values of RTE and GSU were similar (87.8% vs. 83.1%). RTE was better at detecting Gleason grade above 7 than GSU (70.8% vs. 47.4%).

A further study by Brock and colleagues (2013) analyzed a combined approach of RTE and contrast-enhanced ultrasound (CEUS)-multiparametric ultrasound. Eighty-six patients with biopsy-proven prostate cancer were included. Imaging results were correlated with final pathologic evaluation on whole-mount slides after radical prostatectomy. RTE had a sensitivity and specificity of detecting prostate cancer of 49% and 73.6%, respectively. Of 86 target lesions identified by RTE, 58 (67.4%) showed a suspicious perfusion pattern on CEUS, 31 (36%) showed hypoperfusion, and 27 (31.4%) showed hyperperfused tissue. Normoperfusion was found in 28 identified target lesions (32.6%). Prostate cancer was found in 65.1% (56 of 86) of these lesions. CEUS revealed suspicious perfusion patterns in

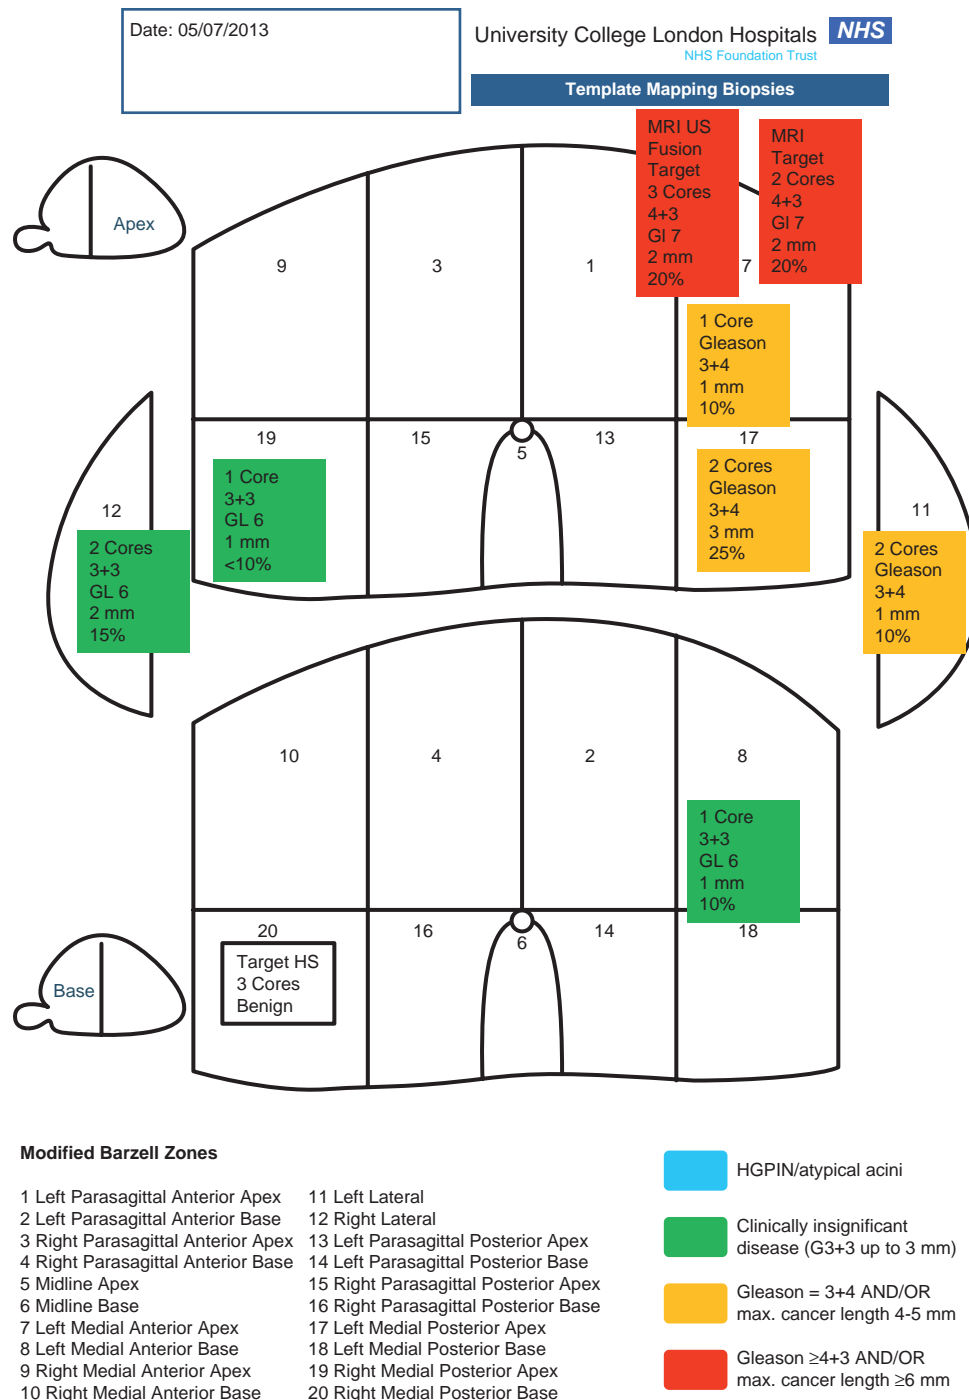

Figure 117-12. A zonal map depicting the results from a modified Barzell zone transperineal template prostate mapping case. The index lesion is on the left with UCL/Ahmed definition clinically significant cancer 1 and 2 on the left and clinically insignificant cancer on the right in two zones. The two high-risk areas (red) on the left were obtained through targeted biopsies based on the information provided by multiparametric magnetic resonance imaging.

92.9% of these lesions—either hypoperfusion (48.2%) or hyperperfusion (44.6%). Overall, if an RTE-positive target lesion showed a suspicious perfusion pattern, the likelihood of detecting cancer was 89.7%. A combination of RTE followed by CEUS reduced the false-positive detection rate from 34.9% to 10.3%.

Walz et al (2011) specifically evaluated the accuracy of RTE in identifying the index lesion for focal therapy in 32 patients. Criteria for the index lesion defined by this study were as follows: the largest suspicious lesion on RTE; on biopsy data, the lesion present in the lobe with positive cores (if the contralateral lobe had no positive

cores); the lobe with the higher percentage of positive cores or the higher percentage of cancer on core length (if positive cores were present in both lobes); and/or the lobe with the higher Gleason score. Of all patients, 87.5% had clinically significant prostate cancer defined as Gleason pattern 4 or 5 and/or cancer volume exceeding 0.5 mL and/or extraprostatic extension. The sensitivity, specificity, negative predictive value, positive predictive value, and accuracy of RTE alone were 58.8%, 43.3%, 54.1%, 48.1%, and 51.6%, respectively. TRUS biopsies alone achieved 67.8%, 48.4%, 56.8%, 60.0%, and 58.1%, respectively. The combination of RTE

and biopsy data increased these values to 84.9%, 48.4%, 61.9%, 75.0%, and 66.1%. Overall, however, RTE alone would miss 40% of index lesions. This study did not perform target biopsies of the suspicious lesions observed on RTE, making it difficult to predict whether a combination of RTE-targeted biopsies with systematic biopsies may have increased accuracy to detect the index lesion.

There have been a few studies reporting on PHS. [Hamann and colleagues \(2013\)](#) looked at 80 men who consecutively underwent a systematic 14-core prostate biopsy supplemented by three PHS-targeted TRUS and transperineal biopsies. Twenty-eight men (35%) were found to have cancer. Targeted transperineal biopsy detected more lesions than targeted TRUS (82.1% vs. 53.6%). However, systematic TRUS and targeted transperineal biopsies performed almost equally in the detection of cancer (22 vs. 23; $P > .99$). The study was unable to report on the accuracy of PHS. [De Coninck and colleagues \(2013\)](#) compared random systematic biopsies with targeted PHS lesions; 58% of lesions suspicious on PHS were positive for cancer. However, the TRUS biopsy detected only 13% of cancers, much lower than standard TRUS detection rates of 45% to 50%, which calls into question the biopsy technique used.

[Javed and colleagues \(2014\)](#) reported on the ability of PHS to detect and localize prostate cancer compared with TRUS biopsy and transperineal biopsy. Tumor volumes of PHS-predicted lesions were also analyzed on radical prostatectomy histopathologic analysis. PHS had a sensitivity and specificity of 100% and 5.9%, respectively, when compared with TRUS biopsy. Compared with transperineal biopsy, PHS had a sensitivity and specificity for cancer detection in the posterior gland of 100% and 13%, respectively, and for the anterior gland, 6% and 82%, respectively. There was no correlation between total tumor volume estimates from PHS and radical prostatectomy specimens. Sensitivity and specificity of PHS for detecting tumor foci 0.2 mL or greater in volume were 63% and 53%, respectively. The estimated sensitivity for PHS to detect tumor greater than 0.5 mL was 37%. Index lesions were also biopsied, although no definition was given for the features of the index lesion—that is, cancer core length or Gleason grade. There was no correlation between measured tumor volume of suspected index lesions detected by PHS and radical prostatectomy histopathologic examination. These findings suggest that PHS is poor at localizing prostate cancer, assessing tumor burden, and detecting small foci of disease.

Multiparametric Magnetic Resonance Imaging

Recent innovations in MRI are also a further attempt to accurately localize prostate cancer extent without the need for invasive procedures and associated morbidity.

Multiparametric magnetic resonance imaging (mpMRI) involves different imaging parameters including T2-weighted imaging (T2W), dynamic contrast-enhanced (DCE) imaging, diffusion-weighted imaging (DWI), and magnetic resonance spectroscopy (MRS). On T2W, water appears bright, fat appears dark, and prostate cancer appears as areas of low signal. DCE images are rapidly acquired after administration of intravenous contrast. Uptake and release of contrast is more rapid in prostate cancer owing to the increased vasculature compared with surrounding tissues. DWI reflects the differential movement of water within tissues, according to their tissue architecture, cell density, cell membrane integrity, and presence of necrosis. Prostate cancer has restricted diffusion, appearing bright on longer b-value sequences and dark on an apparent diffusion coefficient map. MRS portrays the concentration of choline, citrate, and creatinine. The ratio of choline and creatinine to citrate is increased in prostate cancer ([Kurth et al, 2011](#)). The sensitivity and specificity of mpMRI have been reported to be 93% and 98%, respectively, in detecting and excluding high-grade cancers greater than 0.5 mL in volume ([Ukimura et al, 2013](#)). There are several ways to target based on the outputs of mpMRI—namely, in-bore MRI-guided biopsy, cognitive targeted biopsies, and magnetic resonance imaging-ultrasound (MRI-US) fusion-guided biopsy.

Magnetic Resonance Imaging-Guided Biopsy. A few studies have reported on real-time MRI guidance of needle biopsy. [Durmuş](#)

[and colleagues \(2013\)](#) performed MRI-guided biopsy on 87 patients. The needle guide was directed at the suspicious lesions on prebiopsy MRI, and then sagittal and oblique T2-weighted rapid acquisition was performed. Prostate cancer was diagnosed in 36 (41%) patients; 47% of these had a Gleason grade 7 or higher detected by MRI-guided biopsy. The whole gland was not sampled, so the true sensitivity and specificity of MRI-guided biopsy was not calculated. Another study found that in 15 of 27 (55.6%) patients, prostate cancer was detected by MRI-guided prostate biopsy. However no further characteristics were given regarding Gleason grade ([Anastasiadis et al, 2006](#)). A further study on 68 patients found a cancer detection rate of 59% ([Hambrock et al, 2010](#)). Radical prostatectomy was carried out in 20 of the 40 patients with tumor. Gleason grade 7 or higher was found in 50% of patients; 50% had tumor volume greater than 0.5 mL with Gleason grade 6. Limitations of MRI-guided biopsy include a lengthy process, because prebiopsy, real-time, and postbiopsy imaging have to be performed. There are also only a few centers equipped to perform this type of biopsy.

Cognitive Targeted Biopsies. Several studies have reported on use of mpMRI to target biopsies (MRI-TB). Cognitive targeted biopsies involve the physician reviewing magnetic resonance images to target suspicious lesions on MRI using ultrasound guidance. A recent systematic review comparing MRI-targeted biopsy versus systematic TRUS published by [Moore and colleagues \(2013\)](#) found a similar detection rate between these techniques. MRI-targeted cores had an overall cancer detection rate of 30% versus 7% of systematic cores (368 of 5441). MRI was not suspicious in 38% of men (225 of 599); 23% of these had cancer on a standard biopsy. However, crucially, only 2.3% of these had clinically significant cancer (broadly defined as greater than 5-mm cancer core length and/or any Gleason pattern greater than 3), which would have been missed by an approach targeting MRI lesions alone.

[Kasivisvanathan and colleagues \(2013\)](#) compared the accuracy of MRI-TB versus whole-gland systematic TPM biopsy using different definitions of clinically significant cancer. Using UCL definition 2 (maximum cancer core length 4 mm or more and/or Gleason grade 3+4 or greater), MRI-TB identified clinically significant cancer in 57% of men (103 of 182) compared with 62% (113 of 182) by TPM. TPM had a lower rate of misclassification of clinically insignificant or no cancer compared with MRI-TB (7% vs. 16%). Using the Goto definition, MRI-TB identified a greater amount of clinically significant cancer compared with TPM (difference 8% [95% CI 0.6 to 14.8], $P = .033$). When using the Harnden and Goto definitions for clinically insignificant cancer, MRI-TB performed better compared with TPM, which was statistically significant.

Magnetic Resonance Imaging-Ultrasound Fusion. Several studies have reported on MRI-US fusion, which involves combining a prebiopsy magnetic resonance image with a live ultrasound image at time of biopsy to guide more accurate biopsies. [Puech and colleagues \(2013\)](#) compared several biopsy strategies to see which was accurate in detecting clinically significant prostate cancer, defined as maximum cancer core length of 3 mm or greater or Gleason grade of 3 or higher. Ninety-five patients with suspicious lesions on MRI underwent 12-core systematic biopsy and 4-core target biopsy (TB) with TRUS guidance, with two cognitive target cores aimed visually (TB-COG) and two target cores using MRI-TRUS fusion software (TB-FUS). Clinically significant prostate cancer was detected by systematic TRUS in 52% ($n = 49$) and by TB in 67% ($n = 64$). In 12 of 51 (24%) MRI targets with positive systematic TRUS and TB results, TB led to Gleason score upgrading. In 79 MRI targets, 47% ($n = 37$) were positive with TB-COG and 53% ($n = 42$) with TB-FUS ($P = .16$). Neither technique was superior for Gleason score assessment. [Delongchamps and colleagues \(2013\)](#) compared the accuracy of visual TBs and computerized rigid and elastic MRI-TRUS fusion system with 10- to 12-core systematic biopsy in 391 patients. Overall, the rigid and elastic system TB performed significantly better than random biopsy ($P = .0065$ and $.0016$, respectively) in detecting overall and higher Gleason score cancer. In this study a TB-only strategy would have avoided unnecessary biopsy in 45% while limiting the number of cores in the other 55%. Another

study also showed that MRI-US fusion–targeted biopsies resulted in 22% additional cases of Gleason 3+4 or higher prostate cancer and 67% additional cases of clinically significant prostate cancer (Gleason $\geq 4+3$) compared with 12-core systematic biopsy (Siddiqui et al, 2013).

Pinto and colleagues (2011) compared MRI-US fusion–targeted biopsy under electromagnetic tracking with standard 12-core TRUS biopsy in 101 men; 54.4% of men had prostate cancer. Cancer was detected in 27.9%, 66.7%, and 89.5%, respectively, of patients with low, moderate, and high suspicion on MRI of having cancer. MRI-US fusion–guided biopsy performed better in the detection of cancer in MRIs with a low, moderate, and high suspicion of cancer compared with standard 12-core TRUS biopsy (4.8% vs. 3.8%, 20.7% vs. 12.3%, and 53.8% vs. 29.9%, respectively). Overall, MRI-US fusion–guided biopsy detected more cancer per core than standard 12-core TRUS biopsy alone for all levels of suspicion combined (20.6% vs. 11.7%, respectively). Electromagnetic tracking can also aid focal therapy because therapeutic instruments used in cryotherapy, high-intensity focused ultrasound (HIFU) ablation, or brachytherapy can be guided in real time.

The current drawbacks of MRI are its inability to differentiate between prostate cancer and prostatitis, inflammation, or prostatic intraepithelial neoplasia (PIN). MRI-guided biopsy is time-consuming, because patients have to have an initial MRI, which is then repeated at time of biopsy. MRI-US fusion also has some limitations. It relies on accurate prostate segmentation; the prostate needs to be outlined—manually or semiautomatically—on both MRI and ultrasound images (van de Ven and Barentsz, 2013). This segmentation is also a time-consuming task and is operator dependent. The fusion itself, however, is a relatively quick process, taking under 90 seconds in one study (Bubley et al, 2013), with error rates varying from 2.5 mm to 5 mm depending on whether nonrigid or rigid fusion is used.

We recently conducted a systematic review of the literature reporting on image-fusion devices used to guide and target biopsies in the detection of prostate cancer (Valerio et al, 2015) (Figs. 117-13

and 117-14). Fourteen studies used a paired cohort design. A total of 2293 men were included, with a sample size ranging from 13 to 582. Three studies were conducted in biopsy-naïve men, three were conducted in men with a previous negative TRUS biopsy, eight studies reported on a mixed cohort of men who were either biopsy naïve or had undergone a previous prostate biopsy, and one also included men with radiorecurrent disease.

Our systematic review showed that MRI-TRUS image fusion–targeted biopsies detect more clinically significant cancers using fewer cores compared with standard biopsy techniques. Most studies also showed a higher detection of clinically insignificant cancer, although four studies demonstrated a lower detection rate of clinically insignificant cancer by MRI-TRUS image fusion biopsies. The detection of clinically significant disease was 4.8% to 52% for standard biopsy and 13.2% to 50% for MRI-TRUS image fusion–targeted biopsy. Across all studies in which both rates were reported, the use of MRI-TRUS fusion allowed the detection of greater numbers of clinically significant cancers compared with standard biopsy. The absolute difference in detection rate between the two approaches was a median of 6.8% (range +0.9 to +41.4%) and always in favor of the MI-TRUS software-based approach.

There was substantial discrepancy in the definition of clinically significant disease. Only one study did not report the criteria for defining this outcome. In all the remaining studies, the presence of Gleason pattern 4 was considered clinically significant disease. In eight studies, maximum cancer core length was also considered, although the threshold above which clinically significant disease was defined ranged from 3 mm to 10 mm.

The detection rate of any cancer was 14.3% to 59% and 23.7% to 82.1% in the standard biopsy strategy versus MRI-TRUS image fusion biopsy. The absolute difference in overall detection of prostate cancer between the two approaches was median +6.9% in favor of the MRI-TRUS image fusion–targeted biopsy approach (range –8.8% to +53.2%). In four studies, standard biopsies detected more clinically insignificant disease than the software-based approach. MRI-TRUS image fusion biopsies detected 5% to 16.2% additional

Figure 117-13. Targeted biopsies using fusion software can be carried out using either rigid or nonrigid fusion. The error for the rigid fusion is approximately 5 mm and for the nonrigid fusion approximately 2.5 mm. MR, magnetic resonance; TRUS, transrectal ultrasonography. (Courtesy Yipeng Hu and Dean Barratt, UCL SmartTarget.)

Figure 117-14. A nonrigid software fusion system developed for targeted transperineal interventions. The colored lesion is seen in the left anterior and has been precontoured on the area alongside the prostate capsule contour. (Courtesy Yipeng Hu and Dean Barratt, UCL SmartTarget.)

clinically significant cancers that were missed by standard biopsy alone. On the other hand, standard biopsies detected 0% to 12.4% additional clinically significant cancers that were missed by MRI-TRUS fusion biopsies. However, if the study using transperineal mapping biopsies is removed so that the standard biopsy is only a TRUS biopsy approach, this figure stood at 0% to 7%.

In all series, an image fusion approach was more efficient in detecting clinically significant disease. The median number of cores needed to detect one man with clinically significant cancer was 37.1 (interquartile range [IQR], 32.6 to 82.8; range 23.2 to 252) and 9.2 (IQR 4.6 to 24.8; range 4 to 37.7) for standard and MRI-TRUS image fusion–targeted biopsy, respectively. The median difference in number of cores required across the series was 32.1 cores (IQR +28.3 to +57; range +21.4 to +84.8) in favor of the targeted approach. In other words, to detect the same number of clinically significant cancers with standard biopsy, one would need to use approximately four times the number of cores as compared with an image fusion–targeted approach.

Two studies evaluated the outcomes of MRI-TRUS image fusion biopsies versus visual registration–targeted biopsy. One study did not report sufficient information by which to determine the primary outcome measure and a number of the secondary outcome measures. In the only outcome reported—namely, detection of any cancer—MRI-TRUS image fusion biopsies had a higher rate (53% vs. 47%; no *P* value given). The other study evaluated the two targeting approaches in 125 men with 172 targets in total. In a per-target analysis, MRI-TRUS image software biopsies detected more clinically significant cancers (20.3% vs. 15.1%; *P* = .05) and more cancer overall (32% vs. 26.7%; *P* = .14). It also had better efficiency compared with visual registration, requiring 9.8 rather than 13.2 cores to detect 1 man with clinically significant cancer (Wysock et al, 2014). Furthermore, there was no additional usefulness in visual registration targeting, whereas the image fusion approach detected 7.6% additional clinically significant cancers that would have been missed by the visual registration approach. However, the study was underpowered to show the demonstrated absolute difference in detection rate of approximately 5%, as it was powered a priori to demonstrate a 15% difference in detection rate.

For delivery of tissue-preserving focal therapy, accurate localization and characterization of clinically significant prostate cancer must occur. TRUS biopsy is unable to provide such information accurately. Saturation biopsies seem to add only a small additional benefit unless carried out with a template transperineal mapping technique. A transperineal route has several advantages in that it allows systematic coverage of the gland, which provides accurate localization that can be reproduced when providing focal therapy. There have been imaging developments to help improve guidance of biopsies to allow for more accurate sampling. Studies have shown that MRI has a higher sensitivity and specificity compared with TRUS in detecting clinically significant cancer. Targeted biopsies have been shown to detect more clinically significant lesions than random TRUS biopsy with fewer cores taken, with reduced costs from shorter biopsy times and histopathology processing times.

At the heart of the arguments for and against each modality of localization is the need for precision in excluding disease from untreated areas. Greater accuracy up front will logically translate into lower recurrence or de novo disease rates in untreated areas in the long term. Some clinicians and patients may accept the inaccuracy and uncertainty of tools for determining unilaterality—for example, use of TRUS biopsy—to avoid further (expensive and/or morbid) interventions, with the understanding that a higher recurrent or residual cancer rate is found in the untreated side. Provided that the interval between treatment and detection of cancer in the contralateral side is not sufficient for disease progression, patients could then have that side treated.

Biopsy data are commonly used to determine cancer risk. A targeted approach to lesions found on imaging may have an impact on the risk that a particular man is assigned. Features widely used to indicate high risk include Gleason score of 7 or higher, as well as parameters to indicate the amount of cancer, such as maximum cancer core length, maximum percentage cancer, and the number of positive biopsy specimens (Epstein, 2011). However, if a tumor is exposed to a greater sampling density than the rest of the prostate, it is likely that the proportion of cores that are positive, and the maximum cancer core length, will be greater compared with a TRUS

Figure 117-15. A Gleason 3+4 lesion in the left peripheral zone that through transrectal biopsies may be misclassified as very low risk and very high risk 4+4 through a true hit into the central pattern 4 using current risk stratification systems. In reality, the lesion is intermediate risk.

biopsy. In addition, higher Gleason patterns, if truly present, are more likely to be sampled (Fig. 117-15).

If the trend toward image-guided biopsy continues unchecked, it is likely that we will witness a systematic increase in risk attribution in the men subjected to biopsy if the standard criteria for attributing risk are applied (see Fig. 117-15). It is therefore likely that new risk prediction models based on targeted biopsies will be required. As a start to correct what could be regarded as an artificial increase in cancer risk derived from targeted biopsy, a risk stratification system that is independent of the number of positive cores could be considered.

ABLATIVE TECHNOLOGY

There are a number of ablative technologies that could potentially deliver focal therapy (Ahmed et al, 2009b). HIFU and cryosurgery conform closely to the desired attributes and at present are the only two modalities that have retrospective and prospective data demonstrating feasibility of focal ablation, low side effect rates, very good genitourinary preservation rates, and good early cancer control. Photodynamic and interstitial photothermal therapies have both shown promise in single-center studies and are at present undergoing multicenter evaluation (Lindner et al, 2009; Moore et al, 2009). Brachytherapy, stereotactic radiotherapy, irreversible electroporation, radiofrequency ablation (RFA), and toxin injections into the prostate have not been evaluated in a focal therapy protocol but could be delivered in a focal manner, as could magnetic resonance hyperthermia using magnetic nanoparticles (Rubinsky et al, 2008; Salvador-Morales et al, 2009).

Cryotherapy

Cryotherapy is the ablation of tissue by extremely cold temperatures. The first written report of its use was in 19th-century London, where Arnott applied ice-salt mixtures to breast and cervical cancers (Arnott, 1851). Cryotherapy exerts its effects via a number of pathways, namely:

1. Direct cytolysis through extracellular and intracellular ice crystal formation
2. Intracellular dehydration and pH changes
3. Ischemic necrosis via vascular injury
4. Cryoactivation of antitumor immune responses
5. Induction of apoptosis
6. Endothelial damage, which leads to platelet aggregation and microthrombosis

7. Injury that occurs during warming as a result of osmotic cellular swelling and vascular hyperpermeability

A number of factors affect the efficiency of tissue destruction, namely:

1. Velocity of cooling
2. Nadir temperature
3. Freezing duration
4. Velocity of thawing
5. Number of freeze-thaw cycles
6. Presence or absence of large blood vessels, which can act as heat sinks

Overall, a minimum freezing temperature of -40°C for a duration of 3 minutes is sufficient for tumor eradication (Hoffmann and Bischof, 2002). It has also been demonstrated that complete cell death is unlikely at temperatures greater than -20°C , although cells not destroyed by initial freezing to -20°C were destroyed with a second freeze cycle (Tatsutani et al, 1996). Histopathologic changes after cryotherapy in the prostate are divided into an early degenerative phase caused by coagulative necrosis and a later phase of repair—fibrosis, calcification, and hyalinization (Grampsas et al, 1995; Borkowski et al, 1996).

Although this source of energy is known to be very effective against prostate cancer, it was not before significant technologic developments were made that this source of energy became very attractive in prostate cancer. Mainly, third-generation cryotherapy devices are able to use gas-based systems to provide rapid freeze and thaw cycles (Fig. 117-16). Also, manufacturers have been able to develop multiprobe systems while decreasing the size of each cryoprobe, so the precision of ablation could be enhanced (Fig. 117-17). Finally, the toxicity has significantly decreased because of the use of safety measures, such as a continuous urethral warmer during the treatment, and the systematic use of thermocouples for verifying the temperature both in critical surrounding structures and in the treatment area.

Focal cryotherapy to an area of the prostate is delivered under transrectal ultrasound guidance using cryoneedles inserted via the perineum using a brachytherapy grid or in a freehand fashion. In addition, thermocouples are positioned in the same way, normally in the treatment area, in the Denonvilliers fascia, and in other key areas such as the rhabdosphincter and the neurovascular bundles at the discretion of the surgeon. A urethral cystoscopy is warranted before beginning the treatment, to verify the position of the needles; finally, a continuous urethral warmer to protect the urethra is inserted and maintained during the whole procedure (Figs. 117-18 to 117-25). In addition to the standardized technique, in 2008 the American Urological Association released a Best Practice statement to underline the optimal procedural requirements to deliver effective cryotherapy. The panel recommended a double freeze-thaw cycle and the use of rapid freezing up to -40°C with a slow, almost passive, thaw.

High-Intensity Focused Ultrasound

Ultrasound refers to mechanical vibrations above the threshold of human hearing (16 kHz) and has the ability to interact with tissue to produce biologic changes. Applying an alternating voltage across a piezoelectric material such as lead zirconate titanate generates ultrasound (Figs. 117-26 and 117-27). These materials oscillate at the same frequency as the alternating current, causing ultrasound waves that can propagate through tissues. This in turn causes alternating cycles of increased and reduced pressure (compression and rarefaction, respectively). Diagnostic ultrasound usually uses frequencies in the range of 1 to 20 MHz, but therapeutic HIFU uses frequencies of 0.8 to 3.5 MHz with delivery of energy levels within the ultrasound beams that are several times greater than the energy levels within diagnostic ultrasound. Therapeutic ultrasound can be conveniently divided into two broad categories: low intensity (0.125 to 3 W/cm^2) and high intensity ($>5\text{ W/cm}^2$). The former can stimulate normal physiologic responses to injury and accelerate other processes such as the transport of drugs across the skin. High-intensity ultrasound can selectively destroy tissue

Figure 117-22. T2-weighted magnetic resonance imaging (MRI) scan of a 56-year-old man who had a prostate-specific antigen (PSA) level of 8.9 and a negative transrectal ultrasound (TRUS)-guided biopsy in 2008. Subsequently the PSA rose to 16 in 2009 and he underwent another TRUS biopsy, which showed Gleason 3+3 1-mm prostate cancer, so he underwent active surveillance. The PSA again rose to 18 in 2013, and another biopsy showed focal high-grade prostatic intraepithelial neoplasia. Finally, the PSA was 25 in 2014 and the MRI scan shown here was obtained, showing a right anterior lesion.

Figure 117-23. The lesion from the same patient as in [Figure 117-22](#) was confirmed on the other sequences (diffusion-weighted and dynamic contrast). Here, the dynamic contrast-enhanced scan using gadolinium contrast is shown. Targeted transperineal biopsies of this lesion showed four of four cores positive, with Gleason 3+4 and maximum cancer length involvement of 9 mm.

Figure 117-25. Early 2-week contrast-enhanced magnetic resonance imaging after focal cryotherapy in the man from [Figure 117-24](#) showed confluent lack of perfusion in the area of ablation. He had no urinary leakage, and erections were sufficient for penetrative sexual intercourse.

Figure 117-24. The man from [Figures 117-22](#) and [117-23](#) opted for focal cryotherapy after appropriate counseling. This was guided by image fusion so the needles could be placed accurately into lesion and ensure a margin was incorporated into the treatment. *Red* represents lesion contour from magnetic resonance imaging (MRI); *green* represents prostate contour from MRI.

if delivered in a focused manner (Hill and ter Haar, 1995) (Figs. 117-28 and 117-29).

HIFU relies on the physical properties of ultrasound, which allow it to be brought into a tight focus with an acoustic lens, a bowl-shaped transducer, or an electronic phased array. As ultrasound propagates through a tissue, zones of high and low pressure are created. When the energy density at the focus is sufficiently high (during the high-pressure phase), tissue damage occurs. The volume

Figure 117-28. Diagram showing how a beam of high-intensity focused ultrasound causes cell destruction at the focal point but not in the near-field tissue owing to lower energy density.

Figure 117-29. Diagram showing how the high-intensity focused ultrasound pulses are about the shape of cigars or grains of rice; these are placed next to one another with overlap to ensure coverage of targeted tissue.

of ablation (or lesion) after a single HIFU pulse or exposure is small and varies according to transducer characteristics. It is typically shaped like a grain of rice or cigar with dimensions on the order of 1 to 3 mm (transverse) \times 8 to 15 mm (along beam axis). To ablate larger volumes of tissue for the treatment of solid cancers, these lesions are placed adjacent to one another. The two predominant mechanisms of tissue damage are the conversion of mechanical energy into heat, and inertial cavitation. If tissue temperatures are raised above 56° C, then immediate thermal toxicity can occur, provided the temperature is maintained for at least 1 second. This will lead to irreversible cell death from coagulative necrosis. In fact, during HIFU the temperatures achieved are much greater than this, typically above 80° C, so even short exposures can lead to effective cell death. Inertial cavitation occurs at the same time but is neither as controllable nor predictable. It occurs as a result of the alternating cycles of compression and rarefaction. At the time of rarefaction, gas can be drawn out of solution to form bubbles, which then collapse rapidly. The mechanical stress and a degree of thermal injury induce cell necrosis (Kennedy, 2005). Histologically, the tissue changes that occur are homogeneous coagulative necrosis, with an

Figure 117-30. A 65-year-old man with prostate-specific antigen level of 6.5 who was found to have a lesion in the left peripheral zone on prebiopsy magnetic resonance imaging (MRI). This shows the T2-weighted MRI scan.

Figure 117-31. The same man from Figure 117-30 had this lesion confirmed on diffusion and dynamic-contrast magnetic resonance imaging. Here the early-phase contrast image is shown. This area underwent targeted template transperineal biopsies, and one biopsy showed Gleason 3+4 4 mm.

inflammatory response that follows leading to formation of granulation tissue—indicated by the presence of immature fibroblasts and new capillary formation—at the periphery of the necrotic area about a week after treatment. Polymorphonuclear leukocytes migrate deep into the treated tissue, and then at 2 weeks the boundary of the treated region is replaced by proliferative repair tissue. The repair process has not been investigated in detail at the cellular level beyond this time, but imaging techniques using CEUS or MRI show an eventual shrinkage of treated volumes, indicating that the necrotic area has been replaced by fibrous scar tissue.

The placement of the small HIFU lesions requires precise planning for an entire tumor to be ablated reliably. Furthermore, patient movement can lead to areas of viable malignant tissue remaining after treatment, and even in ideal situations other factors can prevent a successful treatment. The most important of these include the heat sink effect and calcification. The heat sink effect relates to one area that overheats in the HIFU pulses' pathway and thus prevents adequate ultrasound propagation to the targeted area; such a phenomenon occurs if the time between HIFU pulses is inadequate for tissue cooling or if an area is high in water content, such as a cyst. In addition, highly vascularized tissues might be more resistant to thermal ablation owing to the heat sink effect of their blood supply. Calcification simply leads to reverberation and shielding of the targeted area from parts of the HIFU pulse, leading to inadequate heating of the tissue. Technical improvements in this field are continuous, and at the time of writing this review, some companies have developed magnetic resonance–TRUS fusion systems for treatment planning purpose and real-time magnetic resonance monitoring during treatment, which are now being validated (Dickinson et al, 2013) (Figs. 117-30 to 117-40).

Regardless the approach and the device used, the technology is the same, and the procedure very similar. In all cases, the patient is under general or spinal anesthesia, a suprapubic or urethral catheter is positioned, and the treatment area is targeted using the available technology (TRUS, MR-TRUS fusion, or in-gantry MRI). In the past, some groups systematically performed transurethral resection of the prostate (TURP), considering the risk of urinary retention to be high; but when HIFU is delivered in a focal manner, this risk is low and TURP should not be part of the standard procedure anymore.

Photodynamic Therapy

Photodynamic therapy (PDT) uses a photosensitizing drug that is activated, after a given drug-light interval, by light of a specific wavelength. It requires tissue oxygen for the treatment effect,

with the activated drug forming reactive oxygen species, which are directly responsible for damage to the treated volume. The photosensitizing drugs are activated either while in the tissue or in the vasculature. Tissue-activated drugs have long drug-light intervals (typically hours to days), which means that the drug and light are given in separate treatment sessions. These drugs usually take a long time to be cleared from the body and can accumulate in the skin, requiring patients to be covered from sunlight (which could activate the drug and cause a sunburn-like reaction) for a few weeks. Some of the tissue-activated photosensitizers accumulate preferentially in tumor tissue. These include aminolevulinic acid (ALA), which is used in the diagnosis of bladder tumors and has also been assessed for use in the treatment of prostate cancer. Vascular-activated drugs have the advantage of a short drug-light interval (i.e., minutes), which allows the whole treatment to be done in a single session. They are usually cleared rapidly from the circulation, without accumulation in the skin, such that light restrictions are not necessary after a few hours.

Light delivery for prostate cancer, along with other interstitial tumors, uses low-power laser light directed to the treatment site by optical fibers. These fibers can deliver light only at the end of the fiber (like a torch) or along a cylindric diffuser (like a strip light). For prostate cancer, a transperineal approach is currently used, with hollow plastic needles placed in the prostate with use of transrectal ultrasound imaging. Cylindric diffusers of the desired length are then placed within the hollow plastic needles, and low-power laser energy, at a wavelength determined by the individual photosensitizer, is delivered to the prostate. Other approaches that have been used are transurethral light delivery and open insertion of fibers at laparotomy.

Focal Photothermal Therapy

Photothermal therapy uses laser fibers with the objective to raise the temperature directly in the treatment area. No photosensitizing agent nor oxygen tissue supply are needed. The ablation effect is claimed to be predictable, accurate, and restricted within the target area. In photothermal therapy, the patient is under general anesthesia or sedated with a urethral catheter placed but removed after the procedure. With a transperineal approach, an open-ended catheter is introduced into the target lesion, and after the correct placement has been verified, an optical laser fiber is inserted to deliver the treatment. Early in the clinical experience, MRI was used for treatment planning, and the placement of the fibers and the treatments were carried out under TRUS guidance. Lately, the use of

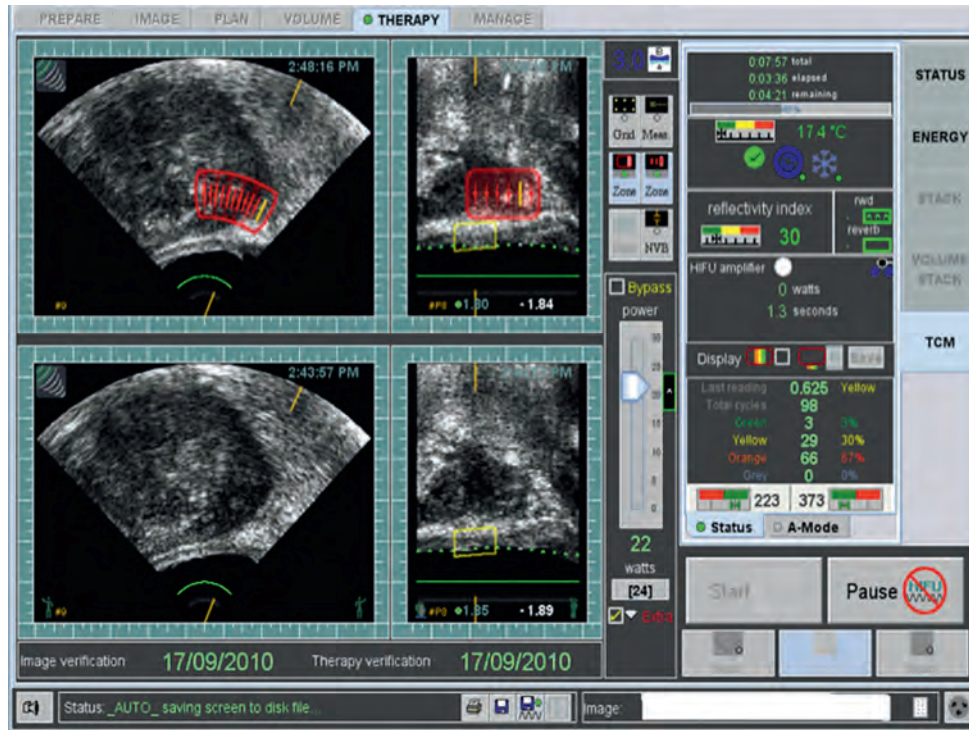

Figure 117-32. Screenshot of the Sonablate high-intensity focused ultrasound (HIFU) device. Treatment is delivered in blocks (red area). The lower two ultrasound images are pre-HIFU baseline images and allow a direct comparison. There are other safety features built into the device to prevent collateral damage. The power of each pulse can be controlled, giving fine control of the energy delivery into the prostate.

Figure 117-33. Post-treatment contrast magnetic resonance imaging in the man from Figures 117-30 to 117-32 shows confluent ablation and some extraprostatic damage, which are quite typical for high-intensity focused ultrasound and point to effect in microscopic extracapsular disease.

Figure 117-34. A 12-month scan from another man who underwent focal high-intensity focused ultrasound (HIFU) and was found to have a suspicious area of recurrence (arrow). This was confirmed on targeted biopsies as Gleason 3+4 2 mm. He chose re-treatment with HIFU in a focal manner.

magnetic resonance-compatible material has allowed in-gantry ablation under real-time MRI monitoring.

Focal Irreversible Electroporation

Irreversible electroporation causes tissue damage by permanently altering the cell homeostasis using low-energy direct current.

Indeed, the use of low voltage avoids local thermal effects and instead forms nanopores in the cellular membrane, which lead to cell death. The energy is delivered to the tissue from the generator to electrode needles inserted around the tumor. Irreversible electroporation has some key features that make it potentially very attractive. First, once the needles have been positioned, the treatment is very quick, usually less than 5 minutes. Second, it seems to

Figure 117-35. Early contrast magnetic resonance imaging after repeated focal high-intensity focused ultrasound shows excellent treatment effect. The patient was found to be cancer free on mapping template biopsies 2 years later.

Figure 117-37. A high b-value ($b = 1500$) axial scan has poor spatial resolution, but when areas have high signal, this indicates clinically significant cancer.

Figure 117-36. A 66-year-old man with a prostate-specific antigen level of 7.5 and normal rectal examination findings underwent prebiopsy magnetic resonance imaging (MRI) as part of a validating cohort trial called the Prostate MRI Imaging Study (PROMIS). This involves prebiopsy MRI that remains blind to the physician and the patient. The patient then undergoes a transrectal biopsy and a template mapping transperineal biopsy at a sampling frame of 5 mm. This image shows a discrete lesion anteriorly on T2-weighted MRI.

Figure 117-38. Contrast-enhanced scans were less helpful on their own, but a ground-glass enhancement was nonetheless concordant with the other sequences.

have tissue selectivity, so because of the different inner structure, nerves are possibly preserved, which is very important in the prostatic tissue given the presence of the neurovascular bundles.

The procedure is similar to the other needle-based sources of energy with the requirement for general anesthesia, a suprapubic or urethral catheter, and the electrode needles placed transperineally under TRUS control using a brachytherapy grid. However, whereas in cryotherapy, PDT, and photothermal therapy the needles are positioned in the treatments area or close to it, in irreversible electroporation the electrode needles are placed at the boundaries of the lesion to preserve the surrounding structures, which are then not in the electrical field (Li et al, 2011). Men are also fully paralyzed to avoid electrical stimulation (Figs. 117-41 to 117-43; also see Figs. 117-36 to 117-39).

Radiofrequency Ablation

RFA acts by converting radiofrequency waves to heat, resulting in thermal damage. High-frequency current flows from the needle electrode to target tissue with resultant ionic agitation and heat-producing molecular friction, denaturation of proteins, and cell membrane disintegration. The cellular and tissue effects of RFA vary with the duration of ablation and the local temperature achieved. This temperature-time dependence was demonstrated by in vitro studies in which irreversible cell injury of benign and malignant human cell lines were heated to 45° C for 60 minutes, 55° C for 5 minutes, and 70° C for 1 minute. These changes take 4 to 6 minutes at temperatures exceeding 50° C and occur almost immediately above 60° C. Temperatures greater than 105° C cause vaporization of tissue, resulting in gas formation and inefficient creation of radiofrequency lesions. The goal of RFA is to induce temperatures of 50° to 100° C throughout the tumor. Histologic analysis after RFA demonstrates typical coagulative necrosis characterized by cell membrane disruption, protein denaturation, and vascular thrombosis. Exophytic tumors that are surrounded by perirenal fat are

Figure 117-40. The template transperineal map confirms the index lesion is this right anterior tumor with Gleason 3+4=7 3 mm. There are low-volume Gleason 3+3=6 areas in the rest of the prostate that magnetic resonance imaging (MRI) could not detect, arguably a good trait for MRI to have.

better treated than central tumors in which vascular structures can act as a heat sink.

In practice, a grounding pad is placed on the patient, and the radiofrequency probe is inserted in the ablation zone. A computer-controlled generator provides an alternating current in the radio wave frequency of the electromagnetic spectrum. Bipolar RFA decreases the risk of accidental burns associated with monopolar RFA. The impedance of the tissue to this monopolar current leads

to local tissue hyperthermia, which is the basis for the cell kill effect. The temperatures reached during RFA depend on the generator's power, tissue impedance, heat conductivity, and heat dissipation via the local circulation. Commercially available RFA units are classified into temperature-based or impedance-based systems. This means that the computer-controlled generator provides energy to the probe based on either the average temperature achieved or the measured impedance of the tissue monitored during ablation.

Figure 117-43. The man from Figures 117-36 to 117-40 underwent focal irreversible electroporation, and this shows that the ablative effect covers where the prostate cancer lesion was previously present.

Figure 117-44. Bipolar radiofrequency ablation can be carried out by the Encage device. (Courtesy Trod Medical).

Impedance rises toward infinity when tissues are desiccated during ablation or when there is charring. RFA technology can also be classified by dry and wet RFA. The latter allows constant infusion of saline during ablation to reduce the degree of charring and thus a premature rise in impedance. Currently, there is one device under evaluation in the prostate space (Figs. 117-44 and 117-45).

Outcomes

Focal Cryotherapy

Most of the actual knowledge regarding the outcomes of focal cryotherapy as first-line treatment comes from the COLD (Cryo On-Line

Database) Registry, an online database supported by a private manufacturer and independently managed by a research company (Watermark, Indianapolis, IN) and a medical advisory board. The registry has no restricted eligibility for patients, who are selected by their surgeon following local guidelines with the approval of the Institutional Review Board.

In a recent report from the COLD Registry, 1160 men were treated with focal cryoablation (Ward and Jones, 2012). In terms of cancer control, the 3-year biochemical disease-free survival (BDFS) was at 75.7%; the positive biopsy rate was 26.3% when considering only the patients who underwent biopsy because of biochemical failure, or 3.7% if the whole cohort of patients is considered the denominator. In terms of functional outcomes, urinary

Figure 117-45. This is a piece of beef “treated” with the Encage device and showing denaturation. Trials are ongoing for use of this device in humans.

incontinence was found in 1.6% of men, whereas 41.9% of men had new erectile dysfunction, and rectourethral fistula occurred in only 0.1% of the patients.

Despite the efforts of the researchers and the large sample size, the COLD Registry has some significant flaws, such as the absence of entry criteria, on-site quality control, and traceability of data as well as lack of patient-reported outcome measures (PROMs). Other small series have reported on outcomes after focal cryotherapy, but no series so far has had a comparative group, and none has had strict design in terms of outcome measures (Onik et al, 2008; Truesdale et al, 2010; Bahn et al, 2012).

Focal High-Intensity Focused Ultrasound

Some prospective development studies have rigorously and systematically evaluated the functional and oncologic outcomes using reliable and objective outcome measures and PROMs (Ahmed et al, 2011a, 2012d). In these trials, the rate of positive biopsies after focal HIFU ranged from 11% to 23%, whereas significant residual disease was found in 0% to 8% of men. Also, potency and continence were preserved in 86% to 95% and 95% to 100% of patients, respectively.

Other studies investigating focal HIFU have reported some interesting findings. In one case series including 12 patients with low-to-intermediate unilateral prostate cancer, with a follow-up of at least 7.5 years, the 5-year BDFS was 90%, and the 10-year BDFS 38%; cancer-specific survival (CSS) was 100% (El Fegoun et al, 2011). Another retrospective study compared the outcomes of focal HIFU with those of whole-gland HIFU in a similar group of patients differing only in tumor laterality (unilateral vs. bilateral) (Muto et al, 2008). No significant difference was seen in positive biopsy rate in the two groups (10.8% vs. 12.7%; $P = .85$).

Focal Photodynamic Therapy

Apart from one stage I study with no intention to completely ablate the tumor, only one stage IIa-b trial evaluating focal PDT using the agent WST-11 has been published so far (Moore et al, 2006; Azzouzi et al, 2013). In this study, optimal parameters for delivering PDT were evaluated along with toxicity in 85 patients having low- to intermediate-risk prostate cancer. Of these men, 68 (80%) had unilateral disease and were then treated by hemiablation according to the protocol standard operating procedure. At 6 months, and considering only the men having hemiablation, negative biopsy results were found in 17.4% to 38.1% of patients, according to the drug dose and the energy light. Based on validated PROMs, 9 patients reported new erectile dysfunction, and urinary symptoms slightly improved after treatment. However, it should be noted that

the functional outcomes refer to the whole study population, including patients having whole-gland treatment; also, no PROM specific for evaluating continence was used.

In summary, focal PDT has been assessed only in a stage IIa-b study with promising results in terms of toxicity and variable results in terms of efficacy. At the time of writing, a stage III (RCT) study comparing the oncologic outcome and the safety profile of PDT against active surveillance in men with very low-risk disease has achieved the recruitment target of 400 patients, with a randomization allocation of 1 : 1. Although many argue that these men do not represent the ideal population for an active treatment because active surveillance is a safe option for them, it needs to be acknowledged that this is the first stage III trial comparing focal therapy with a standard option.

Focal Photothermal Therapy

Photothermal therapy is a strict focal-based modality in which only small areas of cancer are treated. So far, two stage I and one stage IIa trials have been completed using focal photothermal therapy (Lindner et al, 2009, 2013; Oto et al, 2013). Overall, residual disease in the treated area was found in 22% to 33% of men who had a systematic biopsy after treatment. When reported, potency and full continence were preserved in 96% to 100% and 100% of men, respectively, although no specific PROM for continence assessment was used.

Although photothermal therapy is a promising new energy source with excellent genitourinary outcomes, the oncologic results are limited because only small areas of cancer have so far been targeted. Also, despite the small volume ablated, the operative time at the moment is still significant (around 2.5 to 4 hours). The technique would probably benefit from a larger multicenter stage IIb trial to explore the optimal parameters for successfully delivering energy and to explore reproducibility.

Focal Irreversible Electroporation

Only two case series including patients treated by focal irreversible electroporation have been reported (Brausi et al, 2011; Valerio et al, 2014). In the only study with protocol biopsy, residual disease was found in 27% of patients. Erectile function was preserved in 89% to 100%, whereas continence was maintained in 100%. This technology is very promising but is still in the early stage of assessment. A prospective development trial stage IIa using PROMs and targeted biopsy of the treated area will better clarify the short-term outcomes of this technology. We recently systematically reviewed these data.

OVERALL DATA

A number of series were identified evaluating focal therapy in the primary setting (Table 117-2) (Madersbacher et al, 1995; Zlotta et al, 1998; Beerlage et al, 1999; Souchon et al, 2003; Bahn et al, 2006; Moore et al, 2006; Ellis et al, 2007; Onik et al, 2007; Muto et al, 2008; Murat et al, 2009a; Lindner et al, 2010a; Raz et al, 2010; Truesdale et al, 2010; Ahmed et al, 2011a; El Fegoun et al, 2011; Tay et al, 2011; Ahmed et al, 2012d; Bahn et al, 2012; Chopra et al, 2012; Dickinson et al, 2012; Nguyen et al, 2012; Ward and Jones, 2012; Barret et al, 2013; Napoli et al, 2013).

This equates to 2232 men treated with focal therapy and reported in the literature. Six series used cryosurgery, 12 HIFU, 1 PDT, 3 photothermal therapy, 1 radiofrequency interstitial tumor ablation (RITA), and 1 MRI-guided brachytherapy, and 1 incorporated various ablation techniques. Median follow-up periods for the reported focal therapy series are 0 to 10.6 years (overall range 0 to 11.1).

In our systematic review, most of the studies used some form of preoperative MRI in combination with biopsy parameters as criteria to select patients for inclusion; some recent series use this modality for treatment planning (Table 117-3). The latest prospective trials combine mpMRI with template prostate mapping biopsy

to minimize the possibility of leaving significant areas of cancer untreated. Other tools of preoperative assessment that have been used include transrectal Doppler ultrasound. In summary, among the primary selected studies, 2 series used only TRUS biopsy, 2 used TRUS biopsy and Doppler ultrasound, 6 used TRUS biopsy and MRI, and 4 used template prostate mapping and mpMRI. The preoperative assessment was not reported in 11 studies.

Furthermore, all reported series have treated all known areas of cancer, but no reported series have explicitly stated that therapy was

aimed at the index lesion and deliberately left low-volume, low-grade lesions untreated. Of ongoing trials, most are aiming to treat all known areas of cancer, and 3 trials explicitly aim treatment at the index or clinically significant lesions with surveillance of untreated low-volume, low-grade lesions.

In the largest series of 1160 men using cryoablation, and in another series using HIFU with multiple strategies (n = 88), it was not possible to determine the extent of tissue ablation per patient. Either hemiablation or focal ablation was used in the remaining

studies, with 12 using a hemiablation or extended “dog-leg” or “hockey-stick” approach (number of patients, 537; relative percentage of data available, 49%); 16 used focal or zonal ablation (562, 51%), and 3 used bilateral focal ablation when multifocal disease was present (65, 6%). Our systematic review of focal therapy series demonstrated the summary outcomes shown in [Table 117-3](#).

Side Effects, Complications, and Quality of Life

Fourteen series reported hospital stay, with median length of hospital stay of 1 day. Other perioperative outcomes are poorly reported, with only one study using a standardized classification of these outcomes (Dindo-Clavien classification). The most frequent complications, namely urinary retention, urinary stricture, and urinary tract infection, occurred in 0% to 17%, 0% to 5%, and 0% to 17%, respectively. Only five studies actually reported all of these. Urinary functional outcomes were reported using validated questionnaires in nine studies; physician reported rates were used in five studies. **Using validated questionnaires, the pad-free continence rate varies between 95% and 100%, and leak-free rates are reported at 83% to 100% (see [Table 117-3](#)).**

Erectile function is reported using validated questionnaires in 10 and physician reported rates in 3 studies. Considering only trials evaluating focal therapy with “intention to treat,” when validated questionnaires were used, erectile function sufficient for penetration was reported in 54% to 100% of patients (with or without phosphodiesterase type 5 inhibitor [PDE5I] medication). Physician-reported rates were 58.1% to 85%. One study evaluated the systematic use of a vacuum device and oral therapy (penile rehabilitation) after focal cryoablation. The results, based on nonvalidated outcome measures, found an ability to have penetrative sex in 70.6% (24 of 34) potent men. Historical rates of potency preservation after whole-gland cryotherapy have been 10% to 25%.

Rectal toxicity was often poorly reported. Presence or absence of rectourethral fistula, for instance, was explicitly reported in only 10 series. When reported, **rates of fistula were 0% to 1%**; 1 series reported that 1 of 41 men had grade 3 rectal toxicity conservatively managed as a possible rectourethral fistula. Finally, PROMs evaluating overall quality of life are uncommonly used in these studies, with only 3 publications reporting them; in 1 study using hemiablation HIFU, the patients reported stable quality-of-life scores measured using the Functional Assessment of Cancer Therapy–Prostate (FACT-P) instrument, whereas another demonstrated a slight deterioration after focal HIFU using the same instrument.

Cancer Control

Apart from six early feasibility trials that verified the effect of tissue ablation by analysis of radical whole-mount prostatectomy specimens, nine series incorporated routine mandatory post-focal therapy biopsies in their protocol. In the early six series, the ablative technique was delivered to test the safety and pilot the efficacy of the treatment without the specific aim to completely ablate the whole tumor present. In all, 74 men had radical prostatectomy, and residual disease was found in 73 of them.

Of the remaining nine series, in three series only the treated side underwent biopsy, whereas in six series the contralateral side underwent biopsy, too. **When post-therapy biopsies were routinely offered, clinically significant cancer was present in 0% to 17% (total number of men, 202).** When also clinically insignificant cancer was taken into account, and excluding one feasibility trial aiming to evaluate safety rather than ablation, 4% to 50% of men had positive biopsies after treatment (total number of men, 255). When biopsies were offered only “for cause,” overall positive biopsy rates of 13% to 71% were demonstrated for all types of cancer; when considering all patients enrolled in these series, this percentage was 3.7% to 23%. None of these series reported the percentage of significant cancer among patients having biopsy. Two series evaluated the presence of residual tumor in the treated area; this amounted to 3% to 14% when considering only patients having biopsy and 1.7% to 3.9% when the denominator was all treated patients.

Biochemical control using Phoenix criteria was reported in 5 series. Other definitions used were American Society for Therapeutic Radiology and Oncology (ASTRO) (5 series), Stuttgart (1 series), and Phoenix plus PSA velocity over 0.75 ng/mL/yr (1 series). The results ranged from 86.2% at 8 years’ follow-up (318 men) to 60% at 5 years (56 men). PSA tended to decrease by 66% to 80% from baseline to 12 months. With respect to the need for secondary focal treatments, only 12 series reported this at 0% to 34%. Salvage local treatments—in which a different modality was used or if whole-gland therapy was eventually delivered—was reported in 14 series with rates of 0% to 33%. One feasibility trial had higher secondary focal (67%) and salvage treatment (83%); these upper percentages were not considered in the overall range because the intent to treat was not to destroy all tumor. The progression to metastatic disease was not reported in most of the studies, because the follow-up is too short to have a significant percentage of patients developing metastasis. Nevertheless, when it is indicated, it is extremely low (0% to 0.3%). When considering CSS, it is extremely high, as expected with the small numbers and short follow-up inherent in almost all reported series. No man died of prostate cancer after focal therapy in the defined follow-up period. Four men died of other causes in the follow-up period. **Trifecta outcome was reported in 3 studies, and ranged from 50% to 89% (no incontinence of urine; erections sufficient for penetrative sexual intercourse; cancer control at 12 months or more).**

FOLLOW-UP AFTER FOCAL THERAPY

Early feasibility studies demonstrated an absence of rectal toxicity and preservation of genitourinary function in up to 90% to 95% of men ([Ahmed et al, 2011a, 2011d](#)). They demonstrated impotence rates of approximately 15% with little to no incontinence. The studies used a variety of methods to identify unilateral disease including Doppler TRUS biopsies, TRUS alone, and template biopsies and in general showed poor reporting standards owing to their retrospective nature with short follow-up and typically small numbers of patients.

A strategy to evaluate focal therapy should be embedded in trials that ascertain the key medium-term outcome measures that will determine the success or otherwise of this proposed alternative to the standard of care. This is far from easy. The ideal outcomes—metastases and death—require trials of at least 10 years in duration owing to the long lead time bias inherent in the screen-detected population of prostate cancer, so surrogate markers of failure have been proposed within the standards of care. Radical surgery uses a PSA threshold of less than 0.2 ng/mL, and radiotherapy uses the ASTRO Phoenix consensus criteria of two consecutive rises above PSA nadir ([Roach et al, 2006](#)). On the other hand, active surveillance uses clinical, histologic, and biochemical measures of progression, with the last far from being validated ([van As and Parker, 2007](#)).

If focal therapy is to be proposed as a challenge to these existing strategies, it is likely that many of these measures may not be suitable. Although treating the cancer foci, it does so by leaving substantial amounts of prostate tissue untreated ([Figs. 117-46 to 117-48](#)). It cannot achieve unrecordable PSA levels, nor is it easy in such a setting to apply the ASTRO Phoenix criteria. Equally, progression as defined by active surveillance regimens may not readily translate to a man who has had all clinically significant cancer treated using hemiablation but still has 50% of the prostate still present, for instance. In addition, the optimal ablative modality to deliver focal therapy is far from clear, with cryosurgery, HIFU, PDT, photothermal therapy, and brachytherapy all emerging as likely candidates ([Ahmed et al, 2009b](#)). Whether there will be ablative-specific tissue responses that require adjustments in outcome measures is unclear, but will need to be investigated.

Biochemical Outcomes

Conventional therapies have used surrogate end points, primarily biochemical (PSA) outcomes, to determine the success or otherwise

Figure 117-46. Failure or success of local therapies in prostate cancer depends on the margins of treatment, as with all other cancer surgery. Here, the whole prostate is removed and, apart from positive margins that might occur, the tumor is usually cleared along with the whole of the prostate. This can carry risks.

Figure 117-47. A hemiablation conducts a regional ablative template (the entire right side of the prostate) regardless of location, volume, or grade of the tumor. Here the large right peripheral zone lesion is treated with a wide margin but confined to lobe. There is a higher likelihood of complete ablation with less genitourinary toxicity compared with whole-gland treatment.

Figure 117-48. The large right peripheral zone lesion can also be treated a smaller margin in a zonal or focal ablation. There is a lower likelihood of complete ablation that must be balanced with less genitourinary toxicity and the ability to re-treat in a focal manner.

of radical surgery or radiotherapy (ASTRO Consensus Panel, 1997; D'Amico et al, 1998). Radiotherapy definitions tend to overestimate biochemical disease-free survival, in general with a 5-year lag in deeming a treatment failed compared with surgery. Even within these long-established therapies there can be wide variation in definitions used for failure, with over 166 definitions reported in the literature (Cookson et al, 2007). The definition of success for ablative technologies delivered in a whole-gland manner has not reached consensus (Aus, 2006; Ahmed et al, 2009a). Some have adopted ASTRO criteria or modified the acceptable increase above nadir to 1.2 ng/mL (deemed the Stuttgart definition) (Blana et al, 2009). Others, on the other hand, have determined that a PSA nadir upper threshold should be used, although there is no agreement on whether this should be 0.2, 0.4, or 0.5 ng/mL.

With untreated tissue remaining after focal therapy, it would seem unwise to use absolute biochemical parameters or even PSA kinetics alone without a form of standardization against a particular patient's volume of untreated tissue and volume of cancer ablated. PSA will vary according to the ablative technology, whether a particular device was used, the amount of tissue ablated, and any residual tissue that remains. With the last, the untreated tissue may be benign in its entirety or have clinically insignificant areas of low-volume, low-grade cancer that have been deliberately untreated to deliver tissue preservation. The parameters that may prove to be of greater use are discussed in the following sections.

Prostate-Specific Antigen Density

Stamey and colleagues (1987) were the first to correlate PSA serum values and volume of prostatic tissue, showing that the contribution from benign prostatic hyperplastic tissue was 0.30 ng/mL per gram of tissue and 3.5 ng/mL per cm³ of cancer tissue. PSA density may therefore be a good measure because it will allow for adjustment for residual tissue volume after focal therapy.

Nadir Prostate-Specific Antigen

Setting the PSA decrease relative to the percent of tissue ablated may be more pragmatic. The nadir could be defined by the amount of ablated tissue, with $x\%$ ablation leading to $x\%$ or greater decrease in PSA. Any increase from the nadir would need to be defined within the context of phase II 3- to 5-year trials that take into account the natural tendency for benign prostatic tissue growth and therefore PSA to increase with age (Vesely et al, 2003). The nadir could also be defined in a more intuitive manner by taking into account the proportion of pretreatment PSA that was likely to be attributed to the ablated tumor and the proportion secreted by ablated normal tissue. An accurate determination of cancer volume on MRI or ultrasound can aid in this calculation, whereas derived cancer volumes can be obtained from template TPM biopsies. This is likely to lead to a more robust PSA nadir so that 50% total tissue ablation is likely to lead to a PSA nadir less than 50% of pretreatment PSA, as the contribution to the total PSA is disproportionately higher from cancer tissue. This is borne out by early data from hemiablation strategies, which show a mean decrease of 80% in PSA occurring.

Prostate-Specific Antigen Kinetics

PSA kinetics (velocity [e.g., 1 ng/mL/yr] and doubling time [e.g., ≤ 2 to 3 years]) has been shown to be of some value in determining failure in evaluating progression in active surveillance (Dall'Era et al, 2008). Future trials will need to evaluate the PSA velocity and PSA doubling times that are predictive of failure, as well as velocity and doubling time adjusted for degree of prostate tissue remaining (PSA density kinetics).

Histologic Outcomes

Biopsies should be used to determine absence of disease within treated areas to verify short-term focal ablative success as well

as untreated areas to detect recurrent and de novo disease, respectively, in the medium to long term. However, TRUS-guided biopsies, if used for the latter objective, will be subject to the same systematic and random errors inherent in this test when applied in diagnosis of prostate cancer. So, a degree of targeting using noninvasive imaging to identify clinically significant lesions may be necessary. TRUS-guided biopsies used in this setting are also prone to detect clinically insignificant cancers (low volume, low grade), which are unlikely to influence disease progression; such foci may indeed have been missed on initial localization strategies (Ahmed, 2009). Therefore, their subsequent detection many years after focal therapy need not necessarily equate to the verdict of progressive, recurrent, or de novo cancer. Definitions related to clinical significance would need to take account of grade and cancer core length involvement as in diagnostic strategies—2 to 3 mm of cancer in any one core with absence of Gleason pattern 4 may be a starting point (O'Donnell and Parker, 2008), but such criteria will need careful validation. In addition, more accurate volume assessments of cancer foci, if present on surveillance imaging, will be needed. If they are not visualized on surveillance imaging, a post-treatment template transperineal mapping biopsy may be required to determine the disease burden of any cancer found on surveillance biopsies (Onik et al, 2009).

Biopsies will need to also take into account the therapeutic strategy used at baseline. Was the strategy one of ablating all measurable disease with absence of any cancer in untreated areas, or was some element of cancer accepted in untreated areas, for example, absence of any clinically significant areas (up to 3-mm low-volume, low-grade foci accepted)? In addition, were template mapping biopsies or TRUS-guided biopsies used to localize disease? If the latter, then disease found on surveillance biopsies may simply represent the sampling error of the initial localization tool used.

In summary, biopsies of the prostate for surveillance after focal therapy must be used in a more refined and accurate manner, taking into account the localization and therapeutic strategy used. Image-based targeting and, where necessary, template or saturation biopsies should be used in a similar manner to that before focal therapy. The key determination will be whether recurrence or de novo cancer found on surveillance after focal therapy is clinically significant or insignificant, with the latter triggering continued surveillance and the former warranting further treatment. Indeed, the need and chronology of further treatment may be an ideal parameter against which to assess focal therapy if the comparator arm is active surveillance, although such a determinant of failure is less obvious when radical therapies are considered. An outcome that may have application across all therapies and active surveillance is time to hormonal therapy, and this may serve as an important outcome in comparative trials in future.

Imaging Outcomes

Imaging may have a role in the pretreatment selection of focal therapy candidates (Turkbey et al, 2009). Early gadolinium contrast-enhanced MRI, within 1 to 2 weeks of treatment, has been shown to accurately predict areas of necrosis after whole-gland and focal HIFU as well as other modalities such as PDT, thus having a role in early verification of treatment effect (Kirkham et al, 2008). In addition, a number of authors have stated that multifunctional MRI (T2-weighted, dynamic contrast enhancement, diffusion, spectroscopy) seems to meet the ideal attributes for detection of clinically significant cancer, thus potentially being used to drive the delivery of focal therapy. A number of groups have demonstrated accuracy of over 85% to 90% for lesions that measure 0.2 mL or 0.5 mL in volume. The exclusion of significant lesions may be more important in focal therapy, and hence the negative predictive value; negative predictive values for 0.5-mL lesions have been demonstrated to be as high as 95% if multifunctional MRI is used before TRUS-guided biopsy (Villers et al, 2006; Puech et al, 2009). Because 0.5 mL is commonly used as the threshold at which prostate cancer lesions become clinically significant, the inherent ability of multifunctional MRI to be able

to detect large lesions and not detect small lesions may be its greatest attribute and may serve to justify its use not only in disease localization for focal therapy but also as a triage test before TRUS-guided biopsy (Ahmed et al, 2009a). These results, which used radical prostatectomy reference standard validation, need verification in other centers as part of multicenter trials. In addition, it would be key to also use validation against template mapping biopsies, a reference standard that would have less inherent selection bias owing to its applicability to all men.

It therefore seems logical that, in the medium to long term, surveillance of untreated areas of the prostate could be undertaken by mpMRI to detect recurrence of clinically significant cancer. A negative MRI would imply absence of clinically significant disease that requires no treatment. This would avoid any potential overtreatment after focal therapy. Other ultrasound imaging modalities (elastography, ultrasound tissue characterization [e.g., PHS], CEUS) that are starting to demonstrate promise in the detection of prostate cancer before treatment could also be applied after focal therapy (Hoyt et al, 2008; Atri et al, 2009; Gravas et al, 2009).

SALVAGE THERAPY AFTER RADIORECURRENCE

Over 400,000 men are diagnosed with prostate cancer every year in Europe (Ferlay et al, 2013). Many—estimated at 90,000—undergo primary radiotherapy (Cross and McPhail, 2008). Radiotherapy is an effective treatment in the majority of patients, but approximately 1 in 4 will experience biochemical failure indicated by a rising serum PSA level. Of those men with biochemical failure, half to three quarters have localized recurrence (an estimated 10,000 to 15,000) (Lee et al, 1997; Shipley et al, 1999; Kuban et al, 2003; Bannuru et al, 2011). These men might be suitable for further local treatment (Cross and McPhail, 2008). Men with recurrent prostate cancer usually have failure after the age of 65 years and thus have additional comorbidities and problems that have led to a number of quite varied treatment options being available, ranging from watchful waiting with delayed systemic androgen deprivation therapy (ADT) to local salvage therapies such as surgery or ablative therapy. In over 90% of men with recurrent prostate cancer, the strategy used is watchful waiting with delayed systemic ADT (Grossfeld et al, 2002; Agarwal et al, 2008; Boukaram et al, 2010) when indicated. Estimates for eventual ADT use within 5 years vary (50% to 90%) (Lukka et al, 2005; Kuban et al, 2008; Bolla et al, 2009; Kuban et al, 2011; Warde et al, 2011; Arcangeli et al, 2012).

Determination of Failure Using Prostate-Specific Antigen Criteria and Imaging

Serum PSA criteria for failure have a sensitivity and specificity of 60% to 70% (Roach et al, 2006). We and others have shown that mpMRI has high sensitivity (70% to 90%) for the presence of clinically significant disease at the time of biochemical PSA relapse, but the role of mpMRI as a surveillance tool alongside PSA testing is not yet known. Imaging is used to monitor treatments in many other solid-organ cancers, but the paradigm has not yet been accepted in management of prostate cancer until now. Kara and colleagues (2011) compared the role of DCE MRI (1.5T MRI) with TRUS in the follow-up (18 months from radiotherapy) of 172 patients who were treated with external beam radiotherapy (EBRT). The sensitivity and specificity of TRUS and T2-weighted MRI differed significantly—53.3% and 60% versus 86% and 100%—although the sensitivity of DCE MRI was greatest at 93% with a specificity of 100%. Haider and colleagues (2008) evaluated the role of mpMRI versus sextant biopsy in 33 men. On a sextant basis, DCE MRI had significantly better sensitivity (72% vs. 38%), positive predictive value (46% vs. 24%), and negative predictive value (95% vs. 88%) than T2-weighted MRI. Specificities were high for both DCE MRI and T2-weighted MRI (85% vs. 80%). TRUS biopsy, however, was the reference standard in these studies. MRI-targeted biopsies as well as whole-gland TPM biopsy studies from the UCL

group have shown promising accuracy rates in identifying radiorecurrent disease (Arumainayagam et al, 2010). One study looking at 26 men with biochemical failure after radiotherapy found that there was a similar rate of detection between MRI-targeted biopsies and TPM for clinically significant cancer: 85% (22 of 26 patients) compared with 92% (24 of 26 patients), respectively (unpublished data). These data indicate that a comparative effectiveness study is necessary.

Watchful Waiting with Androgen Deprivation Therapy

Watchful waiting with ADT is quite common (Berge et al, 2007). ADT provides symptomatic control but has limitations. First, it is palliative in intent (Pagliarulo et al, 2012; Payne et al, 2013; Heidenreich et al, 2014b). Second, there are common side effects. These include hot flushes (50% to 80%); breast tenderness or enlargement (up to 60%); lethargy (most); erectile dysfunction or decreased libido (10% to 17%) (Potosky et al, 2001); osteopenia or osteoporosis with consequent fracture (19%) (Shahinian et al, 2005); variable cognitive impairment (Jamadar et al, 2012); symptomatic anemia (13%) (Strum et al, 1997); metabolic syndrome (>50%) (Braga-Basaria et al, 2006); obesity, hyperglycemia, or diabetes (11%) (Derweesh et al, 2007); and cardiovascular disease (5%) (Saigal et al, 2007; Thomas and Neal, 2013).

Third, ADT is expensive, costing thousands per patient over his lifetime. In fact, because ADT does not cure the cancer, after an average of 2 years the cancer cells change and become resistant to ADT (so-called castration resistance). When this happens, new drugs are prescribed that can improve survival by a few months. However, these drugs carry a risk of more side effects and are very costly (tens of thousands of dollars every year). For instance, an incremental cost-effectiveness ratio (ICER) of many thousands of dollars per QALY is required compared with nonhormonal palliation (Bayoumi et al, 2000; National Institute for Health and Care Excellence [NICE], 2008; Lu et al, 2012) (approximately €8000 to €30,000 per year).

Detecting Distant Disease

Bone Scan

After primary treatment of prostate cancer, bone is the first site of relapse in more than 80% of patients. Plain film and bone scans form the mainstay of detection. Bone scans are able to detect metastases up to 18 months before plain film. There needs to be only a 10% change in bone mineral turnover to be detected by bone scans, whereas the bone must demineralize by 50% before a lesion is detected by plain film (Taoka et al, 2001). Bone scans and plain film have been shown to underestimate the true incidence of metastatic disease. Bubendorf and colleagues (2000) performed autopsies on 1589 men with prostate cancer (47% were unsuspected), and the incidence of metastatic bone disease was 90%. Bone scans are also well known for their high rate of false positives resulting from degenerative changes, inflammation, Paget disease, and trauma.

Choline Positron Emission Tomography/Computed Tomography Scan

A significant development in positron emission tomography (PET) radiopharmaceuticals has occurred. Several radiotracers able to visualize different tumor metabolisms are currently available, including fluorine-18 (^{18}F) fluorodeoxyglucose (FDG) for glucose metabolism; carbon 11 (^{11}C)/ ^{18}F -labeled choline and ^{11}C -acetate for lipid metabolism; ^{11}C -methionine for amino acid metabolism; and deoxy- ^{18}F -fluorothymidine for imaging cell proliferation (Picchio et al, 2011).

Among the different PET tracers evaluated for prostate cancer imaging, $^{11}\text{C}/^{18}\text{F}$ choline has been particularly investigated. Choline is an essential component of phospholipids of the cell membrane.

Figure 117-49. A choline positron emission tomography/computed tomography scan showing bony pelvic metastasis in a man with radiorecurrent prostate cancer.

Cell proliferation and upregulation of choline kinase are two mechanisms suggested for the increased uptake of this tracer in prostate cancer (Richter et al, 2010). The presence of choline transporters also seems to be involved in the process of its uptake in cancer cells (Müller et al, 2009). ^{18}F -choline has been shown to have a greater sensitivity and accuracy than ^{18}F -FDG PET/CT to detect prostate malignancy: sensitivity 73% versus 31% and accuracy 67% versus 53%, respectively (Hodolic et al, 2013). A high Gleason score and rising PSA level have been shown to increase rates of detection of ^{18}F -fluoromethylcholine (^{18}F -FCH) PET/CT. One study found that ^{18}F -FCH PET/CT detected prostate cancer recurrence in 97% of patients with Gleason score above 7, 82% of patients with Gleason score of 7, and 63% of patients with Gleason score below 7. Forty-three percent of patients in this study had recurrence in the prostatic bed, and 57% of patients had local metastasis. Currently, it is not recommended to perform choline/PET in patients with a PSA value below 1 ng/mL. Also, choline PET/CT has a low spatial resolution and is limited in the identification of small lymph node deposits (Fig. 117-49).

Whole-Body Magnetic Resonance Imaging

Recent advances in MRI have made it possible to image the whole body (WB-MRI) within a reasonable time of 50 to 60 minutes. DCE MRI and DWI complement conventional anatomic MRI techniques and provide a combined approach for assessing cancer anatomy, microstructure, and function. This enables the study of extraskelatal involvement, including lymph nodes and other soft-tissue metastases (Koh et al, 2007; Komori et al, 2007). Also WB-MRI is conducted without irradiation; therefore patients are not exposed to the cumulative radiation exposure of bone scans, plain films, and CT, which is more than several years of natural background radiation (Heliou et al, 2012; Lecouvet et al, 2012).

A few studies have reported good sensitivity and specificity of WB-MRI compared with current imaging tools. Lecouvet and colleagues (2012) compared DWI-WB-MRI with bone scanning, plain films, and CT in 100 patients; 68 were felt to have metastases. The sensitivities of bone scanning with plain films and WB-MRI for detecting bone metastases were 86% and 98% to 100%, respectively ($P < .04$), and specificities were 98% and 98% to 100%, respectively. The sensitivities of CT and WB-MRI for detecting enlarged lymph nodes were similar, at 77% to 82% for both; specificities were 95% to 96% and 96% to 98%, respectively. Sensitivities of the combination of bone scan and plain films plus CT versus WB-MRI for detecting bone metastases and/or enlarged lymph nodes were 84% and 91% to 94%, respectively ($P = .03$ to $.10$); specificities were 94% to 97% and 91% to 96%, respectively.

Another study compared the detection rate of metastatic disease by WB-MRI with bone scan in 39 patients diagnosed with local prostate cancer. It is interesting to note that the sensitivity for detection of skeletal metastases for both bone scan and WB-MRI was 70% (95% CI 0.42 to 0.98); the specificity was 100%, and the positive predictive value was 100%. WB-MRI and bone scan differed in the areas of detection. For instance, 7 patients had bone metastases on bone scan and 7 had skeletal metastases by WB-MRI, with concordant findings in only 4. Bone scan detected more rib metastases, whereas MRI identified more metastatic lesions in the spine (Venkitaraman et al, 2009). This study showed that WB-MRI and bone scan have similar specificity and sensitivity but may have to be used as complementary investigations to detect skeletal metastases from prostate cancer, rather than as alternatives.

The recognized limitations of these studies is that histology confirmation was not the reference standard because bone biopsies are not common practice and lymph node dissection is recommended only in patients who are suitable for further salvage therapy.

Biopsy of Radiorecurrent Cancer

Positive biopsies are currently the only way to confirm local relapse. However, it is well known that false-positive results can be observed owing to difficulties in distinguishing radiation-induced atypia of benign glands from malignancy (Bostwick et al, 1982; Miller et al, 1993; Crook et al, 2000). Tumor resolution after radiotherapy has no identifiable glandular morphology, and these remnants can be given a high Gleason score. Postradiotherapy prostate biopsies should be evaluated by a pathologist who is familiar with these findings (Boukaram et al, 2010; Kimura et al, 2010).

The time after radiotherapy at which to perform prostate biopsy was discussed previously. Crook and colleagues (2000) showed that 34% of positive biopsies that are obtained 12 months after radiotherapy convert to negative status by 24 to 30 months, whereas about 20% of the patients who have a negative post-treatment biopsy will later experience positive rebiopsy. Scardino (1983) also demonstrated a similar rate of 32% of men with a positive 12-month biopsy result transitioning to negative by 24 months. False negatives have been ascribed to sampling error, whereas false positives and indeterminate biopsies also frequently occur as a result of delayed tumor regression. These “false-positive” biopsies might be one of the reasons for possibly overdiagnosing radiorecurrent prostate cancer. Overall, these studies indicate that biopsies should take place at least 24 to 36 months after radiotherapy.

Transrectal Ultrasound-Guided Biopsy

Although TRUS systematic 10- to 12-core biopsies are standard care, they have inherent inaccuracies as a diagnostic strategy. In the setting of radiorecurrent disease, these errors can equally lead to inappropriate therapeutic decisions. First, TRUS biopsies miss clinically significant disease that is present. Second, they misclassify significant disease as insignificant. These two errors may lead to a man being recommended to effectively undergo palliative care with expectant management and hormones rather than potentially curative local therapy. Third, TRUS biopsies detect small-volume clinically insignificant disease that may inappropriately be attributed as the cause of biochemical failure when, in fact, micrometastases are present. This could lead to unnecessary local salvage therapy that carries variable rates of complications and side effects.

Transperineal Biopsies

Transperineal template prostate mapping biopsies have been shown to be more accurate in detecting both primary and radiorecurrent disease. TPM biopsies involve use of a 5-mm brachytherapy grid applied to the perineum and a TRUS probe to visualize the prostate. Biopsy cores are taken every 5 to 10 mm, with two biopsy cores taken in the same grid coordinate to cover mid-gland to base if the full length of the gland is not covered by one biopsy core. In a treatment-naïve prostate gland, 5-mm TPM has been shown to be

a more accurate diagnostic method when compared with current standard TRUS biopsy.

Magnetic Resonance Imaging for Diagnosing Local Recurrence

Kara and colleagues (2011) compared the role of DCE MRI (1.5T MRI) with TRUS in the follow-up (18 months from radiotherapy) of 172 patients who were treated with EBRT. The sensitivity and specificity of TRUS and T2-weighted MRI differed significantly—53.3% and 60% versus 86% and 100%—although the sensitivity of DCE MRI was greatest at 93% with a specificity of 100%. Haider and coworkers (2008) evaluated the role of mpMRI against sextant biopsy in 33 men. On a sextant basis, DCE MRI had significantly better sensitivity (72% vs. 38%), positive predictive value (46% vs. 24%), and negative predictive value (95% vs. 88%) than T2-weighted MRI. Specificities were high for both DCE MRI and T2-weighted MRI: 85% versus 80%. TRUS biopsy, however, was the reference standard in these studies. This is a poor reference standard compared with whole-mount histology and whole-gland transperineal template prostate mapping biopsies, so these results must be interpreted with some caution.

MRI-targeted biopsies as well as whole-gland TPM biopsies have shown promising accuracy rates in identifying radiorecurrent disease (Arumainayagam et al, 2010). One study looking at 26 men with biochemical failure after EBRT found that there was a similar rate of detection between MRI-targeted biopsies and TPM for clinically significant cancer detection: 85% (22 of 26 patients) compared with 92% (24 of 26 patients), respectively (Kanthabalan et al, 2013).

Whole-Gland Salvage Therapy

An alternative approach is further local treatment, so-called salvage therapy (Dudderidge et al, 2007). Whole-gland salvage surgery (radical prostatectomy or cystoprostatectomy) may be potentially curative but carries a high risk of side effects. These are rectal injury (5% to 10%) (requiring further major open reconstructive surgery) and incontinence necessitating use of pads (>50%), as well as poor quality of life (Bianco et al, 2005; Touma et al, 2005; Sanderson et al, 2006; Boukaram et al, 2010; Kimura et al, 2010; Chade et al, 2012; Yuh et al, 2014; Zugor et al, 2014). These occur because of the close proximity of nerves, muscle, and other organs, which inevitably have collateral damage because even keyhole surgery is not precise enough to overcome the fibrosis and scarring that result from the previous radiation. As a result, there is very poor uptake of this technique even if minimally invasive therapies such as cryotherapy are used (Table 117-4) (Ahmed et al, 2005; Galosi et al, 2007; Ismail et al, 2007; Ng et al, 2007; Pisters et al, 2008; Mouraviev et al, 2012; Spiess et al, 2013) and HIFU (Gelet et al, 2004; Rebillard et al, 2008; Zacharakis et al, 2008; Chalasani et al, 2009; Murat et al, 2009b; Berge et al, 2010; Ahmed et al, 2012b).

Salvage Radical Prostatectomy

Salvage radical prostatectomy offers satisfactory oncologic control with BDFS of 31% to 69% at 5 years and at 30% to 43% at 10 years (Bianco et al, 2005; Touma et al, 2005). However, this salvage method is not often performed owing to the high risks of morbidity. Complications such as incontinence (10% to 80%), anastomotic stricture (17% to 32%), and rectal injuries (3.3% to 50%) stem from fibrosis, merging of tissue planes used for dissection, and poor wound healing caused by radiotherapy. Studies reporting these outcomes have all emphasized the importance of an experienced surgeon because of the high technical demand.

Whole-Gland Salvage Brachytherapy

A number of studies have shown good CSS with salvage brachytherapy for radiorecurrent disease. Grado and colleagues (1999)

TABLE 117-4 Whole-Gland Salvage Outcome Summary

WHOLE-GLAND MODALITY	BIOCHEMICAL DISEASE-FREE SURVIVAL RATES	INCONTINENCE	RECTOURETHRAL FISTULA	FURTHER ENDOSCOPIC INTERVENTION
Radical prostatectomy	28%-87%	68%	0%-15%	10.9%-23.9%
High-intensity focused ultrasound (HIFU)	25%-62%	38%-50%	2%-4%	1.3%-36%
Cryotherapy	11%-86%	4.4%-13%	1%-4%	Not available

showed actuarial BDFS at 3 and 5 years for 49 patients to be 48% (95% CI 32% to 63%) and 34% (95% CI 17% to 51%), respectively. Aaronson and colleagues showed rates of 89.5% BDFS over 3 years in a small group of only 24 after exclusion of 14 (Aaronson et al, 2009). Brachytherapy appears to be a potentially useful salvage therapy that needs further evaluation. Common complications include lower urinary tract symptoms, hesitancy, nocturia, rectal bleeding, and frequent bowel movements. A serious complication is a prostatic-rectal fistula, which in one study occurred in 12% of patients. These complications were found to be higher than those of salvage cryotherapy (Ismail et al, 2007; Pisters et al, 2008).

Whole-Gland Salvage Cryotherapy

Salvage cryotherapy has shown good 5-year BDFS (40% to 58%), which can be up to 73% in patients who had low-risk disease before radiotherapy. It must be noted that these studies vary in their definition of biochemical failure (PSA >0.5 ng/mL vs. ASTRO vs. Phoenix definition) (Ahmed et al, 2005; Galosi et al, 2007). With improvements in technique and development of cryotechnology such as thermocouples that monitor the temperature at important sites within the prostate, and a urethral warming device used to prevent tissue sloughing, complication rates have improved, although they can still be high: incontinence 4% to 73%, rectourethral fistula 0% to 3.4%, perineal pain 5.6% to 39.5%, and urinary retention 0% to 67% (Ng et al, 2007; Nguyen et al, 2007). Sloughing and urethral stricture rates have been reduced from 10% to 15% to as low as zero. Erectile dysfunction has not improved (72% to 86%).

Whole-Gland Salvage High-Intensity Focused Ultrasound

A number of studies have looked at HIFU as a potential salvage therapy for radiotherapy failure cases. Murat and colleagues (2009b) treated 167 patients who had radiorecurrent disease with salvage HIFU. Patients were separated into low-, intermediate- and high-risk groups based on preradiotherapy disease risk; progression-free survival rates at 3 years were reported as 53%, 42%, and 25%, respectively. Ahmed and colleagues had 1- and 2-year progression-free survival rates of 62% and 48%, respectively, in patients who achieved a PSA nadir below 0.5 ng/mL (Ahmed et al, 2012b), in men in whom very few selection criteria were applied. Overall, common complications include incontinence (10% to 50%), bladder neck stenosis (17%), retention from urethral stricture (17%), erectile dysfunction (66.2% to 100%), and rectourethral fistula (3% to 16%) (Gelet et al, 2004; Rebillard et al, 2008; Chalasani et al, 2009).

Focal Salvage Therapy

Prior radiotherapy results in decreased vascularity and poor wound healing in tissues surrounding the prostate, so the relative inability of ablative therapies to sharply predict and demarcate boundaries of treatment results in a significantly greater risk of complications than with their primary counterparts. For instance, the treatment of apical lesions that are in close proximity to the urethra could lead to significant urethral and external sphincter damage. Despite good oncologic control, salvage radical prostatectomy is not widely performed owing to high morbidity. Brachytherapy, cryotherapy, and HIFU are also used as salvage

Figure 117-50. A 72-year-old man who had radiotherapy 6 years before presentation. His original disease was low risk. Biochemical failure occurred with a PSA of 3 ng/mL and rising. Multiparametric magnetic resonance imaging (mpMRI) (T2-weighted, diffusion-weighted, dynamic contrast-enhanced) showed left localized unilateral disease confirmed on template prostate mapping biopsy as unilateral Gleason 3+4 with some radiation effect. Bone scan and positron emission tomography/computed tomography were clear for metastases. Here the T2-weighted scan is shown.

therapies, but their long-term oncologic outcome is still unknown and the morbidity is still high. In primary therapy, these latter treatments are currently undergoing evaluation as part of tissue-preserving focal therapy strategies in which they target cancerous lesions in the prostate. Some early data suggest that a similar strategy could be adopted for radiorecurrent disease.

The goal of these ablative therapies is the same: maximum destruction of cancerous tissue with minimal damage to critical surrounding structures such as the urethra, the urinary sphincter, bladder neck, and rectum (Huang et al, 2007). However, potential problems of focal therapy in radiorecurrent disease include accurately localizing recurrent disease within the prostate, the margins of safe treatment that preserve oncologic efficacy while minimizing harm, and strategies of follow-up. These problems are common to the focal therapy story in treatment-naïve disease (Ahmed et al, 2012a) (Figs. 117-50 to 117-54).

Location of Recurrent Disease

There has been some debate regarding the multifocality and location of radiorecurrent disease. Two studies, conducted by Leibovici and colleagues (2012) and Huang and colleagues (2007), examined radical prostatectomy specimens in radiorecurrent disease. They showed that radiorecurrent disease is often bulky, high volume, bilateral (74%), and close to (67% to 74%) or involving the urethra (7%). They concluded that because biopsies were not able to accurately detect radiorecurrent disease, focal therapies might miss important areas of cancers that could lead to progression and metastatic spread.

Figure 117-51. Diffusion-weighted apparent diffusion coefficient scan of same patient as in Figure 117-50.

Figure 117-52. High b-value (1500) diffusion scan of same patient as in Figures 117-50 and 117-51.

Figure 117-53. The same man as Figures 117-50 to 117-52 with significant enhancement in the lesion on dynamic enhancement.

Figure 117-54. The man with radiorecurrent disease in Figures 117-50 to 117-53 underwent focal high-intensity focused ultrasound (HIFU) ablation using a hemiablation strategy. He was impotent before the HIFU treatment, but he remained pad free and leak free following treatment. The dynamic contrast-enhanced magnetic resonance image shows good ablative effect with absence of blood supply in the treated side. Post-treatment PSA values decreased to 0.2 ng/mL, 0.9 ng/mL, 0.5 ng/mL, and 0.03 ng/mL, measured trimonthly.

Huang and coworkers (2007) found that of 46 radical prostatectomy specimens, 90% had cancer foci at the apex. Furthermore, 28% of specimens in this study also had multifocal disease. However, other studies have shown that recurrence occurs at the initial cancer index lesion site (Cellini et al, 2002; Pucar et al, 2007). Cellini and colleagues (2002) found that in 118 patients, areas not initially affected by tumor had no evidence of disease recurrence at a median of 45 months of follow-up. There is a possibility that if only one focus is treated and multifocal disease is present, these areas can develop and metastasize; however, it may be more probable that the index lesion hypothesis may also be relevant in this setting.

We previously discussed the role of TPM biopsies and mpMRI in detection of localized recurrence. These modalities would in theory have the ability to provide 3D data to drive the focal delivery of ablative modalities for focal salvage.

Focal Salvage Brachytherapy

Kaplan and colleagues (2013) looked at the role of MRI fusion imaging to guide focal salvage brachytherapy. Twelve patients with pathologically confirmed recurrence of prostate cancer had MRI-US fusion image-guided intraoperative dosimetry. A median of 42 (range, 30 to 71) seeds containing iodine-125 (^{125}I) or palladium-103 (^{103}Pd) were placed, and isodose distributions were concentrated on the biopsy-proven abnormalities on MRI only. Total prescribed dose was 8000 cGy. Biochemical failure was defined using the previous ASTRO consensus definition. Toxicity was graded according to the Radiation Therapy Oncology Group (RTOG) and Late Effects Normal Tissue (LENT) criteria. Median follow-up after salvage brachytherapy was 48 months (range, 19 to 111). Three of 12 patients had biochemical failure; 4 of 12 patients had grade 2 or 3 RTOG toxicities including subacute grade 3 urinary retention and had grade 3 urinary incontinence after TURP was performed 5 years after salvage brachytherapy. This is a small study that used TRUS biopsy to confirm recurrence as well as the old ASTRO definition to determine biochemical failure. Another study by van Vulpen and colleagues (2012) delivered focal salvage ^{125}I brachytherapy to 16 patients with DCE MRI and biopsy-proven recurrence. Prescription dose to the recurrence was 144 Gy. After 6 months only 1 patient was found to have grade 3 toxicity according to the National Cancer Institute Common Toxicity Criteria.

Focal Salvage Cryotherapy

Eisenberg and colleagues (2008) performed a retrospective study on 19 patients. These patients were selected on the basis that they fulfilled Phoenix definition for biochemical failure, they had TRUS biopsy-confirmed recurrence, the recurrence was unilateral, and their glands were only partially treated with cryotherapy. Fifteen men had longer than 6 months' follow-up, which included trimonthly PSA and TRUS biopsy. The complication rates in this study were low; 1 patient developed mild stress urinary incontinence, 1 developed a urethral stricture that required dilation, and 1 developed a prostatic urethral ulcer managed with suprapubic catheter drainage with resolution after 6 months. Whether this represented a fistula was difficult to determine from the study report. Only 5 patients had available potency data, with 2 men maintaining potency and 3 impotent after treatment. According to the Phoenix definition of failure, 89%, 79%, and 79% of men were free of biochemical recurrence at 1, 2, and 3 years, respectively. Although 19 men were included, only 10 men were rebiopsied, with 90% (9 of 10) having no recurrence at 1-year biopsy. Overall, this was a small study with limited and poor follow-up. Although BDFS rates appeared to be good, not all patients were followed, and only half of these men had a biopsy after salvage treatment.

Focal Salvage High-Intensity Focused Ultrasound

Ahmed and colleagues (2012c) performed focal salvage HIFU in 39 patients. Disease recurrence was confirmed by mpMRI and either TPM (20 men) or TRUS biopsies targeted to the area of recurrence (19 men). Focal HIFU was either hemiablation (ablation of the lobe up to urethra) or quadrant ablation (ablation of one half of the lobe anterior or posterior). Patients with recurrence confirmed by TRUS biopsies underwent hemiablation. If there was multifocal cancer, then the patient underwent index lesion ablation if the untreated areas had 1 core or less with 3 mm or less of maximum 3+3 disease (on TPM) and/or no lesion on mpMRI.

Median follow-up was 17 months. Trimonthly PSA levels were measured, and validated questionnaires including the International Prostate Symptom Score (IPSS), the Expanded Prostate Cancer Index Composite urinary domain, and the International Index of Erectile Function 5-point scale (IIEF-5) were administered. Pad-free, leak-free continence status after treatment was 64%, and the pad-free rate was 87% as measured at last follow-up. Erectile function worsened, with IIEF-5 scores decreasing from a median of 18 to 13 at 6 months.

Twenty-three percent of patients developed Clavien 3b complications, although this was not fully discussed. One patient developed a rectourethral fistula, and this resolved spontaneously after 6 months of suprapubic catheter drainage and colostomy, as confirmed on repeat serial MRI studies and urethrograms, and with clinical symptoms. Forty-four percent achieved a PSA nadir below 0.5 ng/mL and the 1-year, 2-year, and 3-year BDFS rates were 86%, 75%, and 63%, respectively, using Phoenix criteria. However, when biopsy postsalvage was positive and requirement for ADT was included in the definition of failure, these rates decreased to 79%, 67%, and 45%, respectively. For men who did not achieve PSA nadir less than 0.5 ng/mL (56%), the 1-year, 2-year, and 3-year BDFS rates were much lower at 55%, 24%, and 0%, respectively.

Another recent study has shown that 48 patients were prospectively enrolled in two European centers wherein inclusion criteria were biochemical recurrence after primary radiotherapy, positive MRI, and one or more positive biopsies in only one lobe (Baco et al, 2014). Biochemical failure was defined using Phoenix criteria. Patients with obstructive voiding symptoms at the time of treatment underwent an endoscopic bladder neck resection or incision during the same anesthesia to prevent the risk of postoperative obstruction. After hemisalvage HIFU, the mean (standard deviation [SD]) PSA nadir was 0.69 (0.83) ng/mL at a median (interquartile range) follow-up of 16.3 (10.5 to 24.5) months. Disease progression occurred in 16 of 48 (33%). Of these, 4 had local recurrence in the untreated lobe and 4 bilaterally, 6 developed metastases, and 2 had

rising PSA levels without local recurrence or radiologically confirmed metastasis. Progression-free survival rates at 12, 18, and 24 months were 83%, 64%, and 52%, respectively. Severe incontinence occurred in 4 of the 48 patients (8%), 8 (17%) required one pad a day, and 36 of 48 (75%) were pad free. The International Continence Society questionnaire showed a mean (SD) deterioration from 0.7 (2.0) to 2.3 (4.5) for scores A and 0.6 (1.4) to 1.6 (3.0) for B. The mean (SD) IPSS and erectile function (IIEF-5) scores decreased from a mean (SD) of 7.01 (5.6) to 8.6 (5.1) and from 11.2 (8.6) to 7.0 (5.8), respectively. The mean (SD) European Organisation for Research and Treatment of Cancer (EORTC) Quality-of-Life Questionnaire (QLC-30) scores before and after hemisalvage HIFU were 35.7 (8.6) versus 36.8 (8.6). These data seem to again indicate feasibility and early encouraging and acceptable outcomes from a focal salvage strategy (Baco et al, 2014).

With up to one third of men who undergo curative radiation therapy for localized prostate cancer demonstrating biochemical failure within 5 to 8 years, there is a clinical need to find local curative salvage therapies. The irradiated pelvis, resulting in increased treatment toxicity, compromises salvage treatment. Although radical prostatectomy has a good oncologic outcome, it is not often performed owing to the high technical skill required to avoid significant complications, which often occur regardless of surgical skill. Whole-gland salvage ablative therapies have improved, resulting in decreased complication rates; however, their long-term oncologic outcome is still not available, and substantial side effects can still occur.

Through improved methods of detection, including frequent PSA measurements, mpMRI, and targeted image-guided prostate biopsy, as well as novel imaging that may improve the detection of micrometastatic cancer, those with radiorecurrent disease could be better identified. With improvements in localization of disease and the need for decreased toxicity and the avoidance of hormones, focal salvage ablative treatments may have a role. **Focal salvage treatment may provide a potential cure if patients are referred at an early stage when recurrence is suspected.**

At present there are few studies (and those lack robust data), although early signs are that toxicity may be significantly lower than with whole-gland salvage approaches. There is an urgent need for further large, prospective studies involving targeted focal ablative treatments to robustly evaluate harms and benefits of whole-gland and focal salvage therapy with medium- and long-term outcomes.

CONCLUSION

The therapeutic dilemma for men faced with a diagnosis of localized prostate cancer is a difficult one. It is not helped by the inherent inaccuracies of our current diagnostic pathway in which transrectal biopsies are used as the verification test. Tissue-preserving therapy relies on the accurate diagnosis, characterization, and localization of disease within the prostate so that therapy can be targeted to the cancer—something we do all the time with other tumors. Early series have shown that toxicity is very much lower. However, there is still much to determine. Reproducibility and longevity of cancer control are important for both physician and patient confidence. Indeed, with very little in the way of survival advantage for radical therapies versus surveillance in the long term, reproducibility across centers with acceptable disease control rates in the medium term may well be the level of evidence required to change practice.

118 Treatment of Locally Advanced Prostate Cancer

Maxwell V. Meng, MD, and Peter R. Carroll, MD, MPH

Definition

Trends in Incidence and Treatment

Natural History

Radical Prostatectomy

Radiation Therapy

Focal Ablative Therapy

Androgen Deprivation and Its Timing

Management of Delayed Sequelae

Clinical Trials

The widespread application of prostate cancer early-detection efforts in the United States has resulted in both an increased number of prostate cancers diagnosed and the earlier identification of these tumors. Despite the stage migration associated with prostate-specific antigen (PSA) testing and the growing number of low-stage and organ-confined tumors, at least 10% of men with newly diagnosed prostate cancer have locally advanced disease (T3NX/+M0). Although this proportion has declined somewhat, it remains significant and has been relatively constant during the past decade. Those men with locally advanced or metastatic prostate cancer at the time of presentation contribute disproportionately to prostate cancer mortality, and improved treatments for such men could have a significant positive impact on overall morbidity and mortality caused by this disease.

Currently, no consensus exists regarding the optimal management of locally advanced prostate cancer. Unlike with clinically localized and low-grade prostate cancer, for which comparable and excellent outcomes may be achieved with a variety of interventions, treatment of disease with local or regional spread by any single modality is associated with significant risk of recurrent disease. Ongoing interest in and the development and evaluation of combination therapy, as well as improvements in risk assessment, should improve cancer outcomes while minimizing treatment-related morbidity and adverse impact on quality of life in these patients. Two analyses suggest that men with higher-risk disease characteristics may have reductions in cancer-specific mortality and metastatic progression after radical prostatectomy compared with other treatment modalities (Cooperberg et al, 2010; Zelefsky et al, 2010).

DEFINITION

Traditionally, the identification of patients with locally advanced disease was based on clinical examination (e.g., digital rectal examination) and clear evidence of spread outside of the prostate capsule (clinical stage T3a), involvement of the seminal vesicles (cT3b), or involvement of adjacent organs (cT4) (Greene et al, 2002). However, the contemporary use of PSA testing has led to the majority of men diagnosed with prostate cancer initially having nonpalpable cancers (cT1c). **Features other than clinical T stage most often contribute to the identification of men with advanced disease and a concomitant increased risk of failure after primary therapy.** Thus improved methods of risk assessment have facilitated categorization

of men as “high risk” and involve consideration of variables such as serum PSA level and Gleason score in addition to clinical stage. The subsequent discussion focuses on this broader definition of locally advanced disease, with inclusion of those patients with regional or lymph node involvement without distant metastasis (T3-4N±M0).

Contemporary Risk Assessment

Multiple methods are currently available to accurately risk stratify men with prostate cancer (Partin et al, 1997; D’Amico et al, 1999; Tewari et al, 2001; Shariat et al, 2008). The Partin tables were initially constructed in the 1990s and updated in 2001 and 2013, assisting in the preoperative prediction of final pathologic stage in men with clinically localized prostate cancer undergoing radical prostatectomy (Partin et al, 2001; Eifler et al, 2013). Although clinical stage, serum PSA level, and Gleason score individually predict pathologic stage and prognosis, the combination of these three variables increases the accuracy of this assessment. These data continue to illustrate that a significant number of men thought to harbor organ-confined tumors have more advanced disease. The ability to assess pathologic stage permits better pretreatment counseling of patients and more appropriate selection of therapy and consideration of those with more advanced disease for novel clinical trials. **The most important pathologic criteria predicting prognosis after radical prostatectomy are Gleason score, surgical margin status, and presence of non-organ-confined disease (e.g., extracapsular extension, seminal vesicle invasion, lymph node involvement).**

In addition, to help predict pathologic stage, biopsy information has been incorporated into models estimating cancer outcomes, primarily PSA- or biochemical-free survival, after treatment. Whereas biochemical-free survival is a frequent end point of current prostate cancer studies, it merely represents an intermediate surrogate outcome variable; further trials and studies are necessary to confirm the utility of biochemical recurrence as a marker for reduced prostate cancer-specific survival after treatment. The most widely used tools to predict disease recurrence after local therapy are the nomograms developed by Kattan and colleagues (1998, 2000). In all pretreatment nomograms, clinical stage, biopsy Gleason grade, and pretreatment serum PSA level are incorporated to predict the continuous risk of disease progression after definitive local therapy; models for radiation therapy (RT) also include data on use of androgen deprivation (AD), total radiation dose, and combination

treatment (i.e., external beam and permanent brachytherapy). The radical prostatectomy nomogram was based on nearly 1000 patients with clinically localized disease (T1c-T3aNXM0); thus this model is not applicable for those men with evidence of seminal vesicle involvement or regional spread.

KEY POINTS: RISK ASSESSMENT

- Risk assessment is best performed by a combination of serum PSA level, T stage, cancer grade, and extent of cancer on biopsy.
- Imaging plays a limited role in identifying most patients with high-risk features for whom local therapy may fail.

To simplify risk stratification, men with prostate cancer can be grouped into fewer categories but with maintenance of ability to predict disease behavior and response to intervention. D'Amico and colleagues (1998) defined patients at low, intermediate, and high risk for biochemical failure, still based on pretreatment disease characteristics (clinical stage, PSA value, Gleason score). Recurrence after treatment may be due to unrecognized micrometastatic disease or persistence of locoregional disease. Other variations of simplified risk stratification have been developed and validated, with inclusion of features such as ethnicity and pathologic findings (Moul et al, 2001; Cooperberg et al, 2005). The Cancer of the Prostate Risk Assessment score, ranging from 0 to 10, provides another method to assess risk, with each 2-point increase in score doubling the risk of recurrence after prostatectomy. Although men with "low-risk" disease generally do well and are unlikely to have biochemical recurrence, men in the intermediate- and high-risk groups may have widely discrepant outcomes. Therefore men in these groups benefit from more modern and accurate risk prediction models and nomograms (Mitchell et al, 2005).

Imaging Modalities

Although observations on traditional gray-scale ultrasonography can identify extraprostatic disease, the general ability to improve cancer staging is limited (Figs. 118-1 and 118-2). Directed biopsy of the seminal vesicles or prostate capsule can be obtained to confirm cT3 disease. Smith and colleagues (1997) found that transrectal ultrasonography did not improve the ability to stage prostate cancer; the area under the curve was .69 and .74 for transrectal ultrasonography in predicting extracapsular extension and seminal vesicle invasion, respectively, compared with .72 and .69 for digital rectal examination, respectively. Salo and colleagues (1987) reported high sensitivity (86%), specificity (94%), positive predictive value (92%), and negative predictive value (89%) of ultrasonography in predicting extracapsular extension in patients undergoing radical prostatectomy. However, more contemporary studies suggest otherwise, with lower sensitivities (23% to 66%), specificities (46% to 86%), positive predictive values (50% to 62%), and negative predictive values (49% to 69%). The inaccuracy of ultrasound staging for prostate cancer is likely to be the result of significant interobserver variability, often subtle signs of extraprostatic spread, and lower-volume tumors currently diagnosed. In general, transrectal ultrasonography understages rather than over-stages prostate cancer. Newer ultrasound techniques such as color and power Doppler studies are under investigation to determine if observations of abnormal blood flow can increase the ability to detect and stage prostate tumors.

Endorectal magnetic resonance imaging (MRI) uses a magnetic coil placed in the rectum to achieve better visualization of the zonal anatomy of the prostate and may delineate subtle distinctions between T2a/b disease and T3 disease (Fig. 118-3). However, use of MRI alone or in combination with magnetic resonance spectroscopy for tumor staging remains controversial. Variable sensitivities (13% to 91%) and specificities (49% to 97%) have been reported

Figure 118-1. Transrectal ultrasound examination demonstrates increased flow on color Doppler study at the left posterior (*upper panel, arrow*) with corresponding hypoechoic area on gray-scale images (*lower panel, arrow*). Note the left lateral distortion and squaring of the capsule, suggesting extracapsular extension. (Courtesy Dr. Katsuto Shinohara.)

Figure 118-2. Transrectal ultrasound examination demonstrates hypoechoic tumor in the left base (*arrowhead*) with likely extension into the ipsilateral seminal vesicle (*arrow*). (Courtesy Dr. Katsuto Shinohara.)

for predicting extracapsular extension, in part attributed to variability in interpreting MRI and lack of uniform diagnostic criteria. In a cohort of 336 men with more than three cores involved with cancer, abnormal findings on digital rectal examination, and PSA level higher than 10 ng/mL undergoing radical prostatectomy, the specificity of MRI in predicting pT3 disease was 95% (Cornud et al, 2002). Thus the use of MRI may be best limited to those patients with higher-risk features.

Figure 118-3. Axial T2-weighted magnetic resonance image shows tumor involving the seminal vesicle and bladder base and extending into the adjacent fat.

Novel Markers

It is clear that traditional clinical and pathologic parameters are limited in their ability to accurately predict local extent of tumor before treatment. Given the importance of assessing true pathologic stage, novel markers of advanced disease are necessary. [Chu and colleagues \(2003\)](#) used comparative genomic hybridization in primary prostate specimens and identified chromosomal regions potentially useful in discriminating between organ-confined and locally advanced tumors ([Table 118-1](#)). Prediction of stage by a model incorporating six aberrations in a stepwise fashion was accurate in 91.1% of cases. Further metabolic, genetic, and proteomic signatures will likely better define and discriminate between organ-confined and non-organ-confined prostate cancer ([Ashida et al, 2004](#); [Paris et al, 2004](#); [Mehra et al, 2007](#); [Sreekumar et al, 2009](#)). Chromosomal rearrangements involving the androgen-regulated gene *TMPRSS2* and the ETS family genes are associated with higher pathologic stage, whereas the glycine metabolite sarcosine was more often elevated in metabolomic profiles of men with metastatic prostate cancer.

TRENDS IN INCIDENCE AND TREATMENT

Within the Cancer of the Prostate Strategic Urological Research Endeavor (CaPSURE), [Cooperberg and colleagues \(2003\)](#) observed a significant decrease in the fraction of men presenting with high-risk disease characteristics, as defined by D’Amico criteria, from 40.9% in 1989-1990 to 14.8% in 2001-2002. However, alterations in cancer screening and use of PSA screening are likely to account for this reduction, with significantly fewer men presenting with elevations in PSA level higher than 20 ng/mL (32.8% to 7.2%); indeed, currently, higher Gleason grade defines a larger number of high-risk patients (61.5%). Overall, the presence of clinically advanced disease (i.e., T3-4) decreased from 11.8% to 3.5%, with a decline from 32.3% to 21.9% in the high risk group during the observation period. Similar findings were reported from Johns Hopkins, with 69% of men classified as high risk solely by Gleason score in the contemporary cohort (2001-2010) compared with 29% in the earlier cohort (1992-2000) ([Pierorazio et al, 2012](#)). Outcomes over time, however, were comparable with respect to PSA outcomes as well as metastasis-free and cancer-specific survival.

In men undergoing radical prostatectomy, the number with clinical evidence of locally advanced disease as defined by clinical stage (T3) has declined from 25.3% in 1987 to 2.8% in 2001 ([Ward and Zincke, 2003](#)). Although the use of PSA screening can account for part of this change, the more selective application of surgery and improved techniques of RT may also explain the decline in patients with cT3 disease undergoing prostatectomy. Within reports of men undergoing radical prostatectomy, the fraction of men with pT3 disease has decreased; these are highly selected patients with largely clinically localized disease at the time of treatment ([Table 118-2](#)). [Roehl and colleagues \(2004\)](#) reported that pathologically advanced disease decreased from 39% (1983-1991) to 31% (1992-2003). In men undergoing radical prostatectomy alone at the Cleveland Clinic, the overall rate of extracapsular extension declined from 65.8% (1987-1989) to 25.2% (2000-2001), and this trend was true for all clinical stages of tumor (T1c-T2b/c) as well as for pretreatment variables (PSA value, Gleason score).

KEY POINTS: TRENDS IN INCIDENCE AND TREATMENT

- Fewer men are presenting with locally advanced prostate cancer.
- There has been an increase in organ-confined cancers identified after radical prostatectomy.
- There is an increasing use of treatment modalities other than surgery for high-risk prostate cancers.

The [National Comprehensive Cancer Network \(2013, 2014\)](#) provided updated decision trees for men with prostate cancer to aid in treatment selection. High risk of recurrence includes men with clinically advanced disease, both cT3a and cT3b-T4. Bone scans are indicated in these men, as well as in those with PSA level greater than 20 ng/mL or Gleason score 8 or higher; pelvic computed tomography or MRI is also indicated for cT3-T4 disease or if the calculated probability of lymph node involvement is greater than 10%. In general, radical prostatectomy with extended pelvic lymphadenectomy is reserved for those high-risk men with low-volume tumors that can be completely excised. The alternative treatment strategy for these men with locally advanced disease and higher risk of biochemical failure is AD therapy combined with RT. The shift in treatment is also reflected within the CaPSURE database ([Meng et al, 2005](#)). A total of 6074 men with prostate cancer (clinical stage lower than T3aN0M0) were stratified according to risk group, of whom 26% were high risk. Fewer men in this group underwent radical prostatectomy compared with the low-risk cohort, with older age, advanced disease, and increased number of comorbidities significant predictors of treatment (external beam radiation or

AD therapy) in multivariate modeling. In addition, more than half of high-risk men receiving radiation therapy also received AD, significantly more than in the low- and intermediate-risk groups ($P < .0001$). Data from the Surveillance, Epidemiology, and End Results cancer registry between 1998 and 2005 show that nearly half of men with cT3-4M0 prostate cancer receive a combination of AD and RT, while the rate of prostatectomy increased but was only 10% in 2005 (Lowrance et al, 2012).

NATURAL HISTORY

Active surveillance, with deferred treatment when necessary, is becoming a viable treatment alternative in men with prostate cancer. Multiple studies have suggested that cancer-specific mortality is low and primarily associated with higher-grade and higher-stage disease. Even in those low-risk cancers, however, an increased and unexpected progression of disease and associated prostate cancer mortality may be seen during an extended period (Johansson et al, 2004). In men with higher-risk disease characteristics, it has been recognized that disease progression occurs more rapidly and that some form of intervention is typically warranted in healthy patients. Nevertheless, the indications for active surveillance are expanding and appropriate selection may be facilitated by novel genomic tests (Cooperberg et al, 2011; Cary and Cooperberg, 2013).

Few reports address the specific question of outcome in men with locally advanced cancers merely observed for a prolonged period. Older studies such as that from Nesbit and Plumb (1946) have little relevance to current disease management. Other studies have included only a small number of patients with higher clinical stage. A range of clinical progression (22% to 75%), local progression (22% to 84%), and development of distant metastases (27% to 56%) has been reported during 5 and 10 years of follow-up. Overall survival ranging from 10% to 92% at 5 years and from 14% to 78% at 10 years is reported for patients who harbor cancers of high grade or stage. The Veterans Administration Cooperative Urological Research Group (VACURG) study reported a 58% overall 5-year survival in 248 men with clinical stage III disease treated with placebo (Byar, 1973). Comparable survival outcomes were reported within the Medical Research Council (MRC) study (Adib et al, 1997) randomizing previously untreated patients with locally advanced, nonmetastatic disease ($n = 501$) to early or delayed AD therapy (castration or luteinizing hormone-releasing hormone [LHRH] agonist). The median time to clinical progression and

death from prostate cancer in the 244 patients receiving delayed treatment was 10 months and 48 months, respectively.

In the analysis from Chodak and colleagues (1994), grade 3 tumors were significantly associated with disease-specific mortality (risk ratio 10.04) in men treated conservatively, compared with low-grade (grade 1) cancers. The 10-year disease-specific survival was 87% in men with grade 1 or grade 2 tumor and 34% with grade 3 tumor, with metastasis-free survival of 81% for grade 1, 58% for grade 2, and 25% for grade 3 diseases. Johansson and colleagues (1997) prospectively observed 642 men with prostate cancer diagnosed between 1977 and 1984 with any stage of disease. Of those men with clinically localized disease, 11% died of prostate cancer, with corrected 15-year survival comparable for those who received initial and deferred treatment. Conversely, the corrected 15-year survival was 57% in patients with locally advanced cancer. Approximately half of men had well-differentiated tumors, and only 6% of these men died of prostate cancer. Death from prostate cancer increased with moderately differentiated (17%) and poorly differentiated (56%) disease. These data are summarized in Table 118-3.

Albertsen and colleagues (1998) reported the long-term outcomes of watchful waiting in 767 men identified from the Connecticut Tumor Registry with clinically localized prostate cancer (1971-1984). The 15-year cancer-specific mortality in men with Gleason sum 6 was 18% to 30%, compared with the 25% to 59% risk of death from other causes. The chances of death from prostate cancer increased with Gleason score 7 (42% to 70%) and 8-10 (60% to 87%). It is likely that a significant proportion of this cohort had non-organ-confined disease because none of the men underwent PSA testing and therefore they probably had more advanced stages of disease compared with contemporary cohorts. In contrast to the report from Johansson and colleagues (2004), the annual mortality rate from low-grade prostate cancer appears to remain stable beyond 15 years after diagnosis (Albertsen et al, 2005) (Fig. 118-4). Men with high-risk prostate cancer, including those with locally advanced disease, are at significant risk of disease progression and cancer-specific death if left untreated.

RADICAL PROSTATECTOMY

The use of radical prostatectomy for management of locally advanced prostate cancer has decreased. In part, the shift in paradigm is due to the recognition that prostatectomy alone is often

insufficient. In addition, improved risk assessment has permitted better identification of these patients before treatment. Advances in delivery of RT and recognition that combined modality treatment (e.g., RT and AD) improved outcomes compared with monotherapy have further contributed to the migration away from surgery for high-risk and locally advanced tumors. Nevertheless, radical prostatectomy can cure some men with high-risk disease features, and the addition of adjuvant and combined therapy may further improve outcomes of surgery alone.

Surgery for Clinical Stage T3 Prostate Cancer

Several series report outcomes of radical prostatectomy for clinical stage T3 tumors (Table 118-4). In examining all reports, overall survival ranges from 64% to 96% at 5 years, 12.5% to 72% at 10 years, and 20% to 51% at 15 years after treatment. Earlier data reflected less accurate risk assessment and a potentially greater number of patients with unsuspected lymph node metastases and associated earlier progression and death. Less variability exists in more contemporary cohorts, in which the cancer-specific survival rates are 85% to 92% and 79% to 82% at 5 and 10 years, respectively, regardless of adjuvant therapy.

Pound and colleagues (1999) found that a reasonable outcome was possible after prostatectomy for clinical stage T3a disease, with a 52% 8-year recurrence-free survival. Similarly, Ward and Zincke (2003) reported 5- and 10-year cancer-free survival of 60% and 44%, respectively, without application of adjuvant AD. Freedom from local or systemic disease at 5 and 15 years after surgery was 73% and 67%, respectively (Ward et al, 2005). In the 812 patients from the series of Lerner and colleagues (1995), 10-year cancer-specific survival was 80%, with only 31% of men with clinical stage T3 disease dying of prostate cancer 15 years after radical prostatectomy. It is unclear, however, whether surgical intervention improves survival compared with alternative treatment strategies. Another interesting observation from the Mayo Clinic was that clinical over-staging was identified in 27% of patients, consistent with other reported rates of 7% to 26%, suggesting that uniformly excluding patients from prostatectomy on the basis of clinical staging may not be appropriate (Ward et al, 2005). The long-term update from this series demonstrated local recurrence-free, systemic progression-free, and cancer-specific survival of 76%, 72%, and 81%, respectively, at 20 years (Mitchell et al, 2012). Gerber and colleagues (1997) reviewed results in 298 men with clinical stage T3 disease undergoing radical prostatectomy and pelvic lymphadenectomy. Although

§Seven-year figures.

the overall 10-year cancer-specific survival was 57%, an apparent benefit of radical prostatectomy in some men with locally advanced disease was suggested by the increased survival (70%) in those who actually underwent prostatectomy and lymph node dissection. In a high-risk cohort undergoing surgery between 1987 and 2009, 37% had specimen-confined disease (pT2–pT3a) and a nomogram was developed incorporating PSA level, age, clinical stage, and biopsy Gleason sum to predict this with 72% accuracy (Briganti et al, 2012). Many men with clinical stage T3 disease have regional spread and may not benefit from prostatectomy; however, select patients (e.g., lower-volume disease) may benefit because local control may be achieved in most, and complete cancer excision is possible in some men.

Biochemical progression after radical prostatectomy is difficult to assess, given the frequent use of adjuvant therapy (e.g., RT or AD). Without the use of secondary treatment, 5-year biochemical relapse is higher than 60% (van den Ouden et al, 1998). In other series with variable use of adjuvant therapy, 5- and 10-year biochemical progression was observed in 42% to 49% and 59% to 62%, respectively. The impact of adjuvant therapy may be minimal with respect to clinical progression (i.e., biopsy-proven local recurrence or objective distant metastasis) after radical prostatectomy. Rates of clinical progression at 5, 10, and 15 years are 12% to 45%, 39% to 49%, and 50% to 71%, respectively.

Outcomes of Prostatectomy for Pathologically Advanced Disease

A significant minority of patients undergoing radical prostatectomy for clinically organ-confined disease will ultimately be found to have *pathologic* evidence of spread outside the prostate. Although these patients may be expected to have progression and survival rates comparable with those of patients with clinically advanced disease, as defined by grade and serum PSA level, those men who present with clinical stage T3 disease are likely to have greater tumor volume, higher grade, and increased likelihood of regional spread. Currently, the majority of men undergoing prostatectomy for pathologically advanced disease are categorized as high risk on the basis of serum PSA value or biopsy Gleason score. Nevertheless, there is overlap in the groups of men undergoing radical prostatectomy for *clinical* stage T3 and *pathologic* stage T3.

As discussed, pathologic stage after radical prostatectomy provides important prognostic information and is a powerful predictor

of outcome, considering all clinical and pathologic factors (Fig. 118-5). The presence of focal and established extracapsular extension increases the rate of clinical progression from 7% for organ-confined disease to 18% and 35%, respectively, at 5 years. Patients with evidence of seminal vesicle invasion or lymph node metastasis are highly likely to develop clinical progression (86% and 95%, respectively) after radical prostatectomy. In men undergoing radical prostatectomy for clinically organ-confined disease, Hull and colleagues (2002) reported 5-year PSA-free survival of 95%, 76%, 37%, and 18% for men with pathologic organ-confined disease, extracapsular extension, seminal vesicle invasion, and positive lymph nodes, respectively. In multivariate analysis, pathologic parameters increasing the relative risk (RR) for progression included extracapsular extension (RR 2.17 to 2.72), seminal vesicle involvement (RR 2.61), and lymph node involvement (RR 3.31). The presence of a positive surgical margin was associated with the greatest RR (4.37, range 2.90 to 6.58). This reinforces the concept that complete surgical removal of all prostatic tissue, regardless of clinical or pathologic stage, should be accomplished when prostatectomy is undertaken. Even with seminal vesicle invasion, however, men without concomitant lymph node involvement can achieve 15-year cancer-specific survival and biochemical relapse-free rates of 81% and 32%, respectively (Secin et al, 2006).

Biochemical progression after prostatectomy for pathologically advanced tumors depends on the definition applied. Five-year rates of biochemical recurrence have been as high as 65% to 72% when a PSA threshold of 0.2 ng/mL is used; less stringent thresholds such as 0.4 ng/mL may yield recurrence rates of 26% at 5 years and at least 50% at 10 years. In a cohort of 747 men with pT3bN0 tumors identified after prostatectomy, the 10-year biochemical recurrence-free, metastasis-free, and cancer-specific survival rates were approximately 25%, 70%, and 80%, respectively (Pierorazio et al, 2011). Seminal vesicle involvement not only increases the risk of biochemical recurrence but also significantly increases the risk of local recurrence after radical prostatectomy. With prolonged follow-up, Hawkins and colleagues (1995) reported local recurrence in nearly half of patients. This risk appears to be lower in contemporary series of patients because of improved selection of patients for surgery, improved surgical technique, and earlier use of secondary treatment either as adjuvant therapy or at the time of biochemical relapse. The minimally invasive approach has been increasingly applied in higher risk cases, and overall the outcomes appear reasonable and comparable to the open approach. Both oncologic and functional outcomes have not been reported to be significantly different,

Figure 118-5. Probabilities of cancer control after radical prostatectomy based on pathologic stage. ECE, extracapsular extension; N⁺, node positive; OC, organ confined; SVI, seminal vesicle invasion. (Modified from Bianco FJ Jr, Scardino PT, Eastham JA. Radical prostatectomy: long-term cancer control and recovery of sexual and urinary function ["trifecta"]. *Urology* 2005;66:83–94.)

although variability in performing and the extent of pelvic lymphadenectomy require further study (Pierorazio et al, 2013; Punnen et al, 2013).

Predictive models have permitted preoperative estimation of PSA-free survival after prostatectomy. Patients with higher biopsy Gleason score and more elevated serum PSA level are at increased risk of failure after surgery. **Overall, the actuarial PSA-free survival after surgery in high-risk men is approximately 50% at 5 to 7 years.** The validity of the Kattan preoperative nomogram was examined in a community-based cohort of patients undergoing radical prostatectomy (Greene et al, 2004). Interestingly, although the overall concordance index (.68) supported the applicability of the tool to a broad spectrum of patients, the nomogram underestimated recurrence in lower-risk men and overestimated recurrence in men at higher calculated risk. Indeed, up to half of men with Gleason sum 8-10 or higher PSA level (>20 ng/mL) may achieve prolonged disease-free survival with prostatectomy alone. Further refinements of risk assessment and novel markers will help determine which high-risk men and locally advanced tumors truly benefit from aggressive surgical intervention, either alone or in combination with other therapy.

Neoadjuvant Androgen Deprivation

To improve outcomes of radical prostatectomy in men with locally advanced or high-risk tumors, several investigators have assessed the use of neoadjuvant AD (NAD) before radical prostatectomy. In 1944 Vallet reported performing radical perineal prostatectomy after orchiectomy in a 59-year-old man with prostate cancer. Others reported the use and efficacy of diethylstilbestrol (DES) before surgery. In 1964 Scott evaluated the results of NAD in 31 men who were observed for 10 years. The majority of patients (52%) were alive and free of clinical recurrence. The prospective randomized trials of NAD in patients with stage cT1-T3 prostate cancer before radical prostatectomy are summarized in Table 118-5.

KEY POINTS: RADICAL PROSTATECTOMY

- Radical prostatectomy alone can result in cancer-free survival in at least half of men at 8 to 10 years despite clinically advanced disease.
- The risk of cancer recurrence after surgery can be quantitated on the basis of pathologic stage, cancer grade, and surgical margin status.
- Neoadjuvant androgen deprivation therapy before radical prostatectomy does not appear to improve cancer-specific or overall survival.

Various measures of outcome have been evaluated in these studies, including changes in digital rectal examination (clinical stage), appearance of tumor on imaging, detection of micrometastatic or circulating cancer cells, and pathologic features such as T stage, surgical margin and lymph node status, and histopathologic changes. Ultimately, the utility of NAD must be assessed by its impact on disease-specific survival or its current surrogate, biochemical-free survival. It is clear that NAD affects tumor behavior and biology, evaluable by changes in metabolic patterns of atrophy on magnetic resonance spectroscopy, lowering of serum PSA level, and histologic atrophy (fibrosis, vacuolization, glandular collapse). Studies have demonstrated that significant reductions in prostate volume (30% to 50%), tumor volume, and PSA level (90%) are consistently noted, with maximal effects occurring during the first 2 months of treatment. However, conflicting results have been reported with respect to pathologic downstaging after NAD in patients with clinical stage T3 cancer. **Overall, only 20% of such patients have organ-confined disease at the time of radical prostatectomy despite clinical downstaging in 32% to 90%.** Schulman and colleagues (2000) described 402 patients with cT2-T3N0M0 tumors randomized to either radical prostatectomy alone or 3

months of total androgen blockade followed by surgery. Pathologic downstaging was seen more frequently in the neoadjuvant group (15%) than in the prostatectomy-alone group (7%; $P < .01$); however, in men with cT3 disease, there was no difference in pathologic downstaging ($P = .18$) and the incidence of lymph node metastases ($P = .36$) in the neoadjuvant and surgery-alone cohorts. Thus whereas clinical downstaging may occur frequently, **pathologic downstaging is significantly less common after NAD, ranging between 8% and 31%.** Most studies do not show decreased seminal vesicle invasion (Table 118-6). Similarly, rates of lymph node metastases are not altered, with the incidence varying between 3.3% and 16% in both the prostatectomy-alone and NAD groups.

Klotz and colleagues (2003) provided long-term follow-up (median, 6 years) of a prospective randomized trial comparing 3 months of NAD before prostatectomy and surgery alone. There was no overall benefit of NAD as measured by biochemical recurrence (34% to 38%), although in the subgroup of men with PSA level above 20 ng/mL, those receiving NAD had greater PSA-free survival (53%) compared with those undergoing prostatectomy alone (35%, $P = .015$). Southwest Oncology Group (SWOG) 9109 was a phase II feasibility study of 16 weeks of goserelin and flutamide before radical prostatectomy in men with T3-T4N0M0 prostate cancer (Powell et al, 2002). Of the 55 patients who underwent prostatectomy, 31% had seminal vesicle invasion and 19% had lymph node metastasis. Organ-confined disease was identified in 67% of cases. At median follow-up of 6.1 years, 5-year progression-free and overall survival estimates were 70% and 90%, respectively. The study demonstrated the feasibility of 4 months of AD before surgery, with acceptable morbidity and outcomes comparable with RT for this population of patients. Extended follow-up at a median of 10.6

years revealed that only 55% had disease progression, with progression-free survival of 40% and overall survival of 68% (Berghlund et al, 2012).

Studies have also examined the incidence of positive surgical margins in those with cT3 disease. Witjes and colleagues (1997) reported similar rates of positive margins in men receiving NAD and those undergoing radical prostatectomy alone (43% and 59%, respectively; $P = .14$). Van Poppel and colleagues (1995) did not find a statistically significant difference between these groups with respect to positive margins—41.3% in the neoadjuvant cohort and 44% in the surgery-alone group. SWOG 9109 reported positive surgical margins in 30% of patients. In contrast, the randomized and nonrandomized studies of NAD in men with lower clinical stage (cT1-T2) clearly demonstrate a reduction in the rate of positive surgical margins. This advantage has not translated into improved long-term PSA-free survival. **For locally advanced tumors (specifically cT3), current data, both retrospective and prospective, do not support a significant benefit of NAD before surgery (Table 118-7).**

The apparent lack of benefit of NAD before radical prostatectomy in men with both lower-stage and locally advanced prostate cancer may be due to a number of factors. It has been suggested that 3 months of AD may be insufficient to cause an improvement in disease-free survival compared with prostatectomy alone. Meyer and colleagues (1999) followed 680 men treated with radical prostatectomy, of whom 292 received NAD. Although there was no difference in risk of biochemical recurrence between the two groups, patients receiving both an LHRH agonist and antiandrogen for more than 3 months had a significantly lower risk of PSA failure than did those treated with surgery alone (hazard ratio [HR] 0.52,

95% confidence interval [CI] 0.29 to 0.93). Subsequently, the Canadian Urologic Oncology Group (Gleave et al, 2001) randomized patients with clinically localized disease to either 3 or 8 months of NAD before radical prostatectomy. In the 500 patients with pathologic staging, positive surgical margins were identified in 23% of the 3-month group and 12% of the 8-month group ($P = .011$); organ-confined disease was found in 68% and 80% of the 3- and 8-month groups, respectively ($P = .0019$). In addition, the rate of non-specimen-confined disease or lymph node extension was greater in the 3-month group (25.6%) compared with the 8-month group (12.6%). However, despite evidence of continued biochemical and pathologic regression of the tumor between 3 and 8 months, no significant difference in PSA recurrence rates was observed at 4 years. Ongoing studies are evaluating the potential utility of other AD agents prior to surgery, including degarelix, abiraterone, and enzalutamide.

Neoadjuvant Chemotherapy and Chemotherapy–Hormonal Therapy

The role of chemotherapy in the treatment of prostate cancer has primarily been limited to men with the most advanced disease. Taxanes, alone or in combination with other agents, have proved effective in those with hormone-refractory prostate cancer, with significant PSA declines (>50%) in more than half of patients and measurable disease response in 28% to 75% (Oh, 2004). Mitoxantrone plus low-dose steroids has shown benefit in pain relief com-

pared with steroids alone and is approved for use in hormone-refractory disease (Tannock et al, 1996; Kantoff et al, 1999). On the basis of these observations, interest has increased in earlier use of chemotherapy in high-risk patients or those with locally advanced disease. These studies are summarized in Table 118-8.

Pettaway and colleagues (2000) treated 33 higher-risk patients with a 3-month combination regimen consisting of two 6-week cycles of ketoconazole and doxorubicin alternating with vinblastine and estramustine. In addition, concurrent AD was accomplished with an LHRH agonist and antiandrogen. Lower pathologic stage was found in 18% of patients with cT3 disease, and the overall positive surgical margin rate of only 17% suggests that the regimen may have improved the ability to resect the cancer above that achieved with NAD alone. A second report of chemotherapy and hormone therapy before surgery combined 4 to 6 months of NAD with paclitaxel, estramustine, and carboplatin in patients with androgen-dependent, high-risk prostate cancer (Konety et al, 2004). No patients were downstaged to pT0 after neoadjuvant therapy, and organ-confined disease was reported in 36%, with a 22% positive surgical margin rate. Overall, 45% remained without biochemical relapse, defined as PSA level above 0.05 ng/mL on three occasions, at median follow-up of 29 months, and no patient has had documented local recurrence. At 43 months of follow-up, Chi and colleagues (2008) reported a 3% complete pathologic response rate and distant relapse rate of 30% in patients treated with NAD and docetaxel.

Other centers have used chemotherapy without concurrent NAD. At the Cleveland Clinic, 16 patients with locally advanced

†Metastasis-free survival at 10 years.

disease (clinical M0) underwent three cycles of oral estramustine and etoposide and subsequent surgery (Clark et al, 2001). Although grade 3 or grade 4 toxicity was seen in 34% of patients, surgery was not delayed in any individual and surgical outcomes were comparable with those in series of prostatectomy without neoadjuvant therapy. With a median follow-up of 14 months, 88% were free of disease and the early PSA failures occurred in the two patients with lymph node metastases.

Single-agent docetaxel is well tolerated before radical prostatectomy, with minimal toxicity (Oh et al, 2001; Dreicer et al, 2004). No cases of complete pathologic response were observed, but no lymph node metastases were identified in one series, whereas the other reported 11% with organ-confined disease. Two thirds and 24% of patients, respectively, experienced a more than 50% reduction in PSA level in response to docetaxel alone. Similar observations have been made using a novel nanoparticle-based formulation of paclitaxel, with no complete pathologic responses (Shepard et al, 2009). Combination therapy with mitoxantrone or estramustine has been reported in small numbers. Garzotto and colleagues (2010) treated 57 men with docetaxel and dose-escalated mitoxantrone during the 16 weeks prior to surgery. Half of patients were free of relapse at 5 years and the rate of positive surgical margins was 33%. Agents described in recent reports include granulocyte-macrophage colony-stimulating factor and thalidomide (Garcia et al, 2008), as well as the epidermal growth factor receptor inhibitor gefitinib (Vuky et al, 2009). It remains to be determined whether new, targeted agents (e.g., custirsen) and immunotherapy (e.g., sipuleucel-T, ipilimumab) will play a role in the neoadjuvant setting.

Adjuvant Radiation Therapy

Withholding regional or systemic therapy until after the prostate has been removed may (1) prevent delay in time to surgery, (2) reduce operative morbidity, and most importantly (3) identify those men with adverse pathologic features or evidence of residual disease who truly need additional therapy, thereby avoiding over-treatment in those found to have more favorable disease. The

selection of appropriate adjuvant therapy remains difficult because knowledge of the ultimate site of failure (discriminating local-regional from distant recurrence) determines the actual type, timing, and efficacy of such intervention.

Until recently, adjuvant RT was not clearly demonstrated to be beneficial after radical prostatectomy; older studies demonstrated no impact on development of distant metastasis or cancer-specific survival, and more recent data show improved biochemical control. Table 118-9 summarizes selected comparative series of adjuvant RT for pathologically advanced disease. In the matched pair analysis of Valicenti and colleagues (1999), early adjuvant RT was administered within 3 to 6 months of surgery with undetectable PSA; control subjects were observed until PSA recurrence. The reduction in risk of PSA relapse was 88% after adjuvant RT with 5-year PSA-free survival of 89%. Anscher and colleagues (1995) provided long-term follow-up (median, 10 years) in 46 patients receiving adjuvant RT after radical prostatectomy for pT3-T4 tumors. At 10 and 15 years, overall survival and disease-free survival in the RT group were 62% and 62% and 55% and 48%, respectively; these were not statistically different from the rates in the group not receiving adjuvant RT. In addition, development of distant metastases was comparable in the two cohorts. Nevertheless, local control was better after adjuvant RT (82% at 15 years) compared with surgery alone (53%).

The use of adjuvant RT is associated with a range of biochemical-free survival, from 50% to 88% at 5 years. This appears to be an improvement (30% to 50%) compared with the results of surgery alone in high-risk patients. Nevertheless, the benefit of adjuvant RT needed to be proven in appropriately designed clinical trials, of which the European Organisation for Research and Treatment of Cancer (EORTC) 22911 (Bolla et al, 2005) and SWOG 8794 (Thompson et al, 2006) have been reported. Both studies randomized patients with pathologically advanced disease, defined as extraprostatic extension (pT3) and/or positive surgical margins without lymph node metastasis, to either immediate RT or observation after surgery. In EORTC 22911, immediate RT was associated with improved biochemical relapse-free survival (74% vs. 53% without RT, $P < .001$) at 5 years. Similarly, SWOG 8794, with median 10.6 years of follow-up, supported immediate

RT with a nearly 50% reduction in biochemical recurrence (35% vs. 64% without RT; $P < .001$) in those with PSA less than 0.4 ng/mL after prostatectomy. In addition, adjuvant RT significantly reduced the risk of clinical local recurrence in both trials. SWOG 8794 demonstrated a surprisingly low risk of metastatic disease (16%) in patients with adverse pathologic features that was further reduced with adjuvant RT (7%) (Swanson et al, 2007), as well as improved freedom from subsequent AD. Moreover, both metastasis-free and overall survival were improved with adjuvant RT (HR 0.71 and 0.72, respectively) (Thompson et al, 2009). A third randomized, controlled trial studying adjuvant RT for pT3N0 tumors after prostatectomy achieving an undetectable PSA confirmed the benefit with respect to biochemical progression-free survival (HR 0.53) (Wiegel et al, 2009).

The decision to administer adjuvant RT is often based on various adverse pathologic features, not all of which carry the same prognosis; indeed, SWOG 8794 combined extracapsular extension, seminal vesicle invasion, and positive surgical margin within a single classification. Thus it is difficult to assess the outcomes of adjuvant RT when the populations are composed, variably, of those with positive surgical margins, extracapsular extension, seminal vesicle invasion, or a combination of these features. Those men with positive surgical margins are at an increased risk of biochemical recurrence. A decision analytical model examining this question demonstrated that the benefit may be limited to those with high likelihood of recurrent local, rather than distant, disease; thus initial RT was recommended for patients with low- to intermediate-grade disease without evidence of seminal vesicle invasion (Grossfeld et al, 2000). This report suggested that adjuvant RT should be considered in those patients with extensive or multiple positive surgical margins. Secondary analyses of EORTC 22911 also support the role of immediate RT in the specific subset with positive surgical margin (Van der Kwast et al, 2007). The treatment benefit of adjuvant RT was primarily seen in patients with positive surgical margins (HR 0.38, $P < .0001$), whereas no benefit was observed in those with negative margins independent of other risk factors. However, the report from Stephenson and colleagues (2004) suggests that the application of adjuvant RT in a broader group of men may be beneficial; 501 men received salvage RT for biochemical recurrence after radical prostatectomy, and 50% experienced disease progression after treatment at a median follow-up of 45 months. Although higher Gleason score and seminal vesicle invasion were poor prognostic variables in predicting response to salvage RT, selected patients with high-grade disease or other adverse features (e.g., rapid PSA doubling time) could still achieve a durable response. Indeed, more than half of patients with Gleason sum 8-10 and positive surgical margins had a PSA nadir of 0.1 ng/mL or less without subsequent rise above this level. **Thus early use of secondary therapy, be it RT or AD, may be beneficial in locally advanced tumors, as well as at the time of biochemical recurrence in select patients.** However, the optimal timing and how these interventions may differentially affect local control, development of distant disease, and survival remain to be determined. Trock and colleagues (2008) reported an improvement in overall survival in patients with pT3 disease receiving salvage RT, with 5-year overall survival of 98%.

In general, men with seminal vesicle invasion are at significant risk for distant metastasis and may not benefit from local or regional RT; nevertheless, some men with pT3b disease may have local recurrence alone. Valicenti and colleagues (1998b) identified a group of 53 men with pT3bN0 disease undergoing radical prostatectomy, with 35 achieving undetectable PSA after surgery. The biochemical-free survival (3 years) in the 15 patients receiving adjuvant RT was 86% compared with 48% in the 20 men who were observed ($P = .01$). In EORTC 22911, there was no statistically significant predictive impact of seminal vesicle invasion on the benefit from RT as measured by biochemical progression-free survival, regardless of whether PSA was less than or greater than 0.2 ng/mL after surgery (Van der Kwast et al, 2007). However, even with pT3b disease, there was a benefit of adjuvant RT in patients with positive surgical margins. Men in SWOG 8794 with seminal vesicle invasion

receiving RT had improved 10-year biochemical failure-free survival (36% vs. 12% for observation) but no significant improvement in metastasis-free and overall survival. Conversely, subgroup analysis of the ARO trial suggested that extracapsular extension without infiltration of the seminal vesicles was a predictor of better outcome with RT (Wiegel et al, 2014). **On the basis of limited data, it appears that men with seminal vesicle invasion who achieve a low PSA level (<0.3 ng/mL) after prostatectomy or have positive surgical margins may be a more favorable group in whom adjuvant RT may be considered.** Conversely, those men with more advanced disease never reaching an undetectable PSA level generally constitute a poor prognostic group likely harboring unrecognized lymph node or distant disease.

Traditionally, adjuvant RT has been delivered in lower doses compared with the dose for salvage therapy, with the range from 45 Gy to more than 60 Gy. Most contemporary series of adjuvant RT report doses greater than 60 Gy. Valicenti and colleagues (1998a) evaluated the dose response in a small number of patients ($n = 52$) receiving adjuvant RT for pT3N0 disease. The difference in 3-year biochemical-free survival between those treated with less than 61.2 Gy (64%) and more than 61.2 Gy (90%) was statistically significant ($P = .015$), suggesting that higher doses may be necessary. In 27 men with detectable PSA 6 months after prostatectomy, Schild and colleagues (1994) noted that RT doses of 64 Gy or more had improved 30-month freedom from failure (62%) compared with lower RT doses (17%; $P = .03$), supporting the hypothesis of a postoperative RT dose response similar to what has been observed for primary RT in prostate cancer.

KEY POINTS: ADJUVANT RADIATION THERAPY

- Adjuvant radiation therapy improves local control and reduces biochemical relapse in selected patients after radical prostatectomy and likely improves metastasis-free and overall survival.
- The benefit of adjuvant radiation therapy may be greatest in cases of positive surgical margins.
- Improved outcomes of adjuvant radiation therapy are associated with dose escalation (64 Gy).

Adjuvant Androgen Deprivation

Indirect evidence from the MRC and VACURG trials suggesting a benefit of early AD compared with delayed AD in men with various stages of prostate cancer served as the impetus for studying adjuvant AD after radical prostatectomy. In addition, evidence of a benefit of continued AD after therapeutic RT supports a potential role for combined systemic treatment after local therapy in the form of prostatectomy. However, limited clinical data are currently published on this issue in men with locally advanced tumors.

Beyer and colleagues (1993) retrospectively reviewed the outcomes of 86 patients undergoing radical prostatectomy and any form of adjuvant therapy (89% endocrine treatment). In the subset of patients with stage pT3N0 tumors, adjuvant treatment did not demonstrate an advantage with respect to time to progression or survival. Cheng and colleagues (1993) reviewed the Mayo Clinic experience with 1035 patients undergoing radical prostatectomy for pathologic stage C prostate cancer; a significant number ($n = 103$) received adjuvant AD with orchiectomy. Adjuvant therapy of any type (AD or RT) decreased the rate of progression but did not improve cancer-specific or overall survival, with no difference between the two modalities. Prayer-Galetti and colleagues (2000) presented data on 201 men with pT3 disease receiving adjuvant goserelin, demonstrating a 25.4% improvement in disease-free survival at median follow-up of 5 years ($P < .05$).

Recent publications provide some evidence supporting a benefit of early AD after radical prostatectomy in high-risk men with

locoregional disease spread. Zincke and colleagues (2001) retrospectively reviewed data on men with stage pT3b cancer and found that early, adjuvant AD positively affected time to progression and cancer-specific survival. These findings were true not only with seminal vesicle invasion but also with limited lymph node disease, with a 10-year cause-specific survival of 94% after prostatectomy and adjuvant AD with a single positive lymph node. Similar findings arose from the Eastern Cooperative Oncology Group study 7887 randomizing men with nodal metastases after radical prostatectomy (cT1-T2 disease) to immediate (adjuvant) or delayed AD (Messing et al, 1999). At a median follow-up of 11.9 years, men receiving adjuvant AD had improved overall (HR 1.84), cancer-specific (HR 4.09), and progression-free (HR 3.42) survival. A matched pair analysis of men with pT2-4N1 disease treated with prostatectomy suggested that adjuvant AD plus RT yielded significantly higher cancer-specific and overall survival rates at 10 years (86% and 74%, respectively) compared with adjuvant AD alone (70% and 55%, respectively) (Briganti et al, 2011).

RADIATION THERAPY

The contemporary trend is to treat high-risk or locally advanced prostate tumors with methods other than surgery. Although a plethora of studies describe the results of RT for clinical stage C and T3 disease, many were performed before the widespread use of serum PSA determinations for early detection and modern radiation techniques for treatment, such as three-dimensional conformal RT, intensity-modulated RT, and irradiation of the whole pelvis in addition to the prostate (Kupelian et al, 2003). In addition, contemporary data suggest that the optimal radiation dose is higher than that used in previous reports. In higher-risk patients, improved biochemical control has been observed with 81 Gy or more for external beam RT (Zelevsky et al, 2011). An earlier dose escalation trial demonstrated improved outcomes with 78 Gy compared with 70 Gy, with the greatest benefits in the high-risk group with PSA greater than 10 ng/mL (Kuban et al, 2008). In the treatment of men with locally advanced or high-risk prostate tumors, monotherapy with RT or permanent interstitial brachytherapy is likely to be inadequate. Yet it must be emphasized that the outcome measures with demonstrated benefit of AD plus RT compared with RT alone often do not include overall survival. The focus has shifted to improving outcomes by combining RT with AD, often in conjunction with whole-pelvis irradiation (Table 118-10).

Overall survival after RT alone for stage C cancer is approximately 60% to 70% at 5 years and below 50% at 10 years. In high-risk patients, defined by individual parameters alone or in combination, the 5-year progression-free survival rates after RT are typically less than 50%.

Neoadjuvant Androgen Deprivation and Radiation Therapy

The theoretical benefits of AD before RT in men with locally advanced cancers are the ability to reduce target volume and the potential cytotoxic synergy of radiation and hormone manipulation. Several Radiation Therapy Oncology Group (RTOG) trials (75-06, 83-07, 85-19) examined the combination of AD and RT in locally advanced disease, suggesting that the regimen was tolerable and improved local tumor control. On the basis of this information, RTOG 86-10 was designed to compare short-term AD combined with RT with RT alone (Pilepich et al, 2001; Roach et al, 2008). The phase III trial randomized 471 men with cT2-T4 tumors (surface area >25 cm² on rectal examination) to either goserelin plus flutamide for 2 months before and during external beam RT or RT alone. The 4 months of AD were associated with reduction in distant metastases and improvements in local control, disease-free survival, and cancer-specific mortality. At 10 years, the disease-free survival in the AD plus RT and RT-alone groups was 11% and 3%, respectively ($P < .0001$), whereas cancer-specific mortality was 23% and 36%, respectively ($P = .01$). No difference in overall survival between the two groups (43% AD plus RT vs. 34% RT) was found, although

men with lower Gleason sum (2-6) appeared to have a survival benefit from combined AD and RT. In men with Gleason sum 7-10, no significant improvement was observed from AD with respect to locoregional control or survival. Subsequent analysis of RTOG 86-10 (Chakravarti et al, 2003) revealed that loss of p16 expression on immunohistochemistry was associated with reduced overall survival ($P = .039$), disease-specific survival ($P = .006$), and higher risk of local progression ($P = .0007$) and distant metastasis ($P = .026$); overall survival was not significantly associated ($P = .07$) in multivariate analysis. Other correlative studies of tissue from RTOG 86-10 found that the proliferative marker Ki-67 was significantly associated with distant metastasis and cancer-specific survival but not with overall survival (Li et al, 2004).

Similar observations were made by Laverdière and colleagues (1997) in a prospective randomized study of 120 men with cT2b-T4 disease. Treatments included (1) external beam RT alone, (2) 3 months of NAD before RT, and (3) 3 months of NAD before RT and 6 months of adjuvant AD. Evidence of residual cancer on prostate biopsy was present in 62%, 30%, and 4% of the treatment arms, respectively, at 12 months and 65%, 28%, and 5% at 24 months. Biochemical-free survival at 12 and 24 months paralleled the biopsy data, with the difference between the neoadjuvant and adjuvant AD groups disappearing at 24 months. These observations not only supported neoadjuvant and concurrent AD with RT but also suggest a benefit of prolonged AD. In a group of men randomized to either 3 or 8 months of NAD before RT, of whom 31% were categorized as high risk, longer NAD did not improve freedom from or pattern of failure; the only benefit of 8 months of NAD was improved 5-year disease-free survival (71% vs. 42%) (Crook et al, 2009). Long-term outcomes (median 10.6 years) from the Trans-Tasman Radiation Oncology Group (TROG) 96.01 trial demonstrated that 6 months of neoadjuvant AD before RT at 66 Gy was associated with reduced PSA and local progression as well as event-free survival (HR 0.51) in men with cT2b-4N0M0 prostate cancer (Denham et al, 2011). While 3 months of neoadjuvant AD had no effect on distant progression or cancer-specific and all-cause mortality, 6 months of treatment decreased rates of all three compared with RT alone (HR 0.49, 0.49, and 0.63, respectively).

KEY POINTS: NEOADJUVANT ANDROGEN DEPRIVATION AND RADIATION THERAPY

- Neoadjuvant and concurrent androgen deprivation appears to be appropriate in high-risk patients undergoing radiation therapy.
- Adjuvant androgen deprivation after radiation therapy may benefit those with very high-risk disease.

Adjuvant Androgen Deprivation and Radiation Therapy

Several prospective studies have assessed the role of adjuvant AD after RT, as well as the appropriate duration of such therapy. RTOG 85-31 (Pilepich et al, 1997; Lawton et al, 2001) randomized 977 patients with T3NXM0 or T1-T2N+M0 prostate cancer to RT and either goserelin started during the last week of RT and continued indefinitely, or goserelin at the time of relapse (i.e., early or late AD). The groups were matched with respect to disease risk characteristics and fewer than 30% had lymph node involvement. Improved local control and biochemical disease-free and metastasis-free survival were noted in the adjuvant AD group at 8 years of follow-up, and this advantage was most prominent with Gleason sum 8-10. Overall survival was not statistically different at 5 years (75% vs. 72%) and 8 years (49% vs. 42%). In those patients with high-grade tumors, adjuvant AD improved cancer-specific (90% vs. 78%) and overall (80% vs. 69%) survival at 5 years.

In the EORTC 22863 study (Bolla et al, 1997), men undergoing external beam RT for clinically localized disease (cT1-T2 and grade

aAD, adjuvant androgen deprivation; cAD, concurrent androgen deprivation; nAD, neoadjuvant androgen deprivation; p, prostate; PSA, prostate-specific antigen; RT, radiation therapy; WP, whole pelvis.

3, cT3-T4 and any grade) were randomized to RT alone or the addition of goserelin starting at the beginning of treatment and continuing for 3 years. This is the only study to demonstrate an overall survival benefit, with 5-year survival of 79% in the adjuvant AD group and 62% in the RT-alone group ($P = .001$). Disease-free survival was 85% and 48%, respectively, and local control was also improved with AD (97% vs. 79%). Of note, the cohort presented with very high-risk disease, with a median PSA level of 30 ng/mL, and this may account for the relatively low overall survival in the RT-alone cohort.

It does not appear that the method of AD affects the outcome of combined treatment with RT. Granfors and colleagues (1998) randomized men with cT1-T4pN0-3M0 cancer to either external beam RT alone or combined orchiectomy and RT; men treated with RT alone received AD at clinical disease progression. At median follow-up of 9.3 years, clinical progression in the RT-alone and RT-plus-AD patients was 61% and 31%, respectively ($P = .005$). Cancer-specific mortality was not different; overall mortality was

61% and 38%, respectively ($P = .02$). However, in men with negative lymph nodes, there was no significant difference in survival rates, and the poor survival was primarily due to metastatic disease at the time of initial treatment.

A meta-analysis of 2742 men treated for clinically localized prostate cancer within RTOG trials from 1975 to 1992 supports use of adjuvant AD in subsets of patients (Roach et al, 2000). Patients were stratified into four prognostic risk groups, and those in risk group 2 (cT3NX, Gleason 2-6; or cT1-T2NX, Gleason 7; or N+, Gleason 2-6) appeared to have improved disease-specific survival with addition of short-term (4 months) AD. In further refining the population of patients, limiting the analysis to men with bulky or cT3 disease alone demonstrated a significant survival advantage.

If adjuvant AD is of benefit, the duration of such therapy remains uncertain. RTOG 92-02 supports the use of long-term AD after initial AD with external beam RT (Hanks et al, 2003). Men with locally advanced tumors (cT2c-T4N0-1M0) received either 4 months of AD (2 months neoadjuvant and 2 months concurrent) with RT

or that and 24 additional months of AD. Long-term AD was beneficial in all end points evaluated *except* overall survival, with 5-year rates of both approximately 80%. Subset analysis of men with Gleason sum 8-10 noted improved overall survival with 24 months of AD (81%) compared with short-term AD (71%; $P = .044$), as well as improved disease-specific survival; these findings were confirmed during 10-year follow-up (Horwitz et al, 2008). D'Amico and colleagues (2004) described 206 men with clinically localized but higher-risk (PSA ≥ 10 ng/mL, Gleason sum ≥ 7 , cT3) prostate cancer randomized to RT alone (70 Gy) or RT with 6 months of AD. Overall and cancer-specific survival rates were improved with AD compared with RT alone. Actuarial 5-year survival and freedom from salvage AD were 88% and 82%, respectively, after early AD and 78% and 57% with RT alone. **Thus a limited period of AD (2 to 4 months) appears to be appropriate for those men with intermediate-risk cancers; more prolonged AD may be beneficial for those with high-risk disease characteristics, including high-stage cancers, or men with high pretreatment serum PSA values.**

Other aspects of RT for men with more advanced tumors require clarification, including the dose and extent (i.e., prostate only vs. prostate and pelvis) applied. RTOG 94-13 randomized men with an estimated risk of lymph node metastasis of 15% into one of four arms: (1) whole-pelvis RT plus neoadjuvant and concurrent AD, (2) prostate-only RT plus neoadjuvant and concurrent AD, (3) whole-pelvis RT plus adjuvant AD, and (4) prostate-only RT plus adjuvant AD (Roach et al, 2003; Lawton et al, 2007). Initial analysis suggested improved progression-free survival for whole-pelvis compared with prostate-only RT and no difference for the two types of AD. In comparing the four groups after longer follow-up, however, progression-free survival rates were similar, with significant difference only in overall survival among the groups ($P = .027$). Surprisingly, overall survival was worse in patients receiving whole-pelvis RT plus adjuvant AD compared with all other cohorts.

The differences in RT dose among the various prior and contemporary studies make comparisons of efficacy difficult because emerging data support doses greater than 72 Gy as being more effective (Cheung et al, 2005; Jacob et al, 2005). In addition, the role of combined external beam RT and brachytherapy (both permanent and high-dose rate) needs to be better elucidated. Brachytherapy has generally been used to treat patients with lower-risk features. Its use in those with high-risk disease characteristics, often in combination with AD and external beam RT, has been less well studied. Potters and colleagues (2005) noted a 63% biochemical-free survival in those treated with permanent prostate brachytherapy. A similar outcome has been noted with the use of high-dose-rate intensity-modulated brachytherapy with external beam RT (Demanis et al, 2005). Sylvester and colleagues (2003) treated men with interstitial permanent brachytherapy combined with moderate-dose (45 Gy) neoadjuvant external beam RT. In those with high-risk disease (by D'Amico criteria), the 10-year biochemical relapse-free survival was 48%; of note, AD was not used. Stock and colleagues (2004) evaluated a multimodal protocol using neoadjuvant and concomitant AD (9 months total), brachytherapy, and three-dimensional conformal RT in a high-risk cohort. The 5-year biochemical-free survival was 86%, with Gleason sum the only variable associated with PSA failure. Excellent local control was also demonstrated, with no patient harboring cancer on the last post-treatment biopsy.

Radiation Therapy and Chemotherapy

The role of chemotherapy in conjunction with RT is less well studied than that for surgery and chemotherapy. Khil and colleagues (1997) administered estramustine and vinblastine concurrently with RT (total, 65 to 70 Gy) in men with locally advanced disease. Although clinical control was reasonable at 5 years at 81%, only 48% of patients had a PSA level below 4 ng/mL at this time. Zelefsky and colleagues (2000) enrolled 27 patients with high-risk disease (Gleason sum ≥ 8 and PSA > 10 ng/mL; Gleason sum 7 and PSA > 20 ng/mL; cT3N0M0 and PSA > 20 ng/mL; cT4N0M0; cTXN1M0) in a phase II clinical trial of the same agents, with RT at 75.6 Gy.

Only modest increase in grade 2 toxicity was noted, and no late grade 3 or grade 4 toxicities were observed. The 2-year biochemical-free survival was 60%. An update reported median time to PSA relapse of 12 months, with 48% of patients receiving no additional therapy, and median time to metastasis had not been reached (Ryan et al, 2004).

An estramustine-based regimen has also been examined with etoposide before and during definitive RT (Ben-Josef et al, 2001). Actuarial disease-free survival and overall survival were 73% and 88%, respectively, at 3 years. Local control as determined by biopsy was 71% at 18 months. A phase I study examined concurrent docetaxel and RT (70.2 Gy) in 22 men (Kumar et al, 2004). The maximal tolerated dose was determined to be 20 mg/m², with diarrhea and dysuria the primary toxic effects. All patients were alive at last follow-up, and 77% had continued biochemical response. These promising results support further study of the combined use of RT and chemotherapeutic agents.

FOCAL ABLATIVE THERAPY

Advances in technology have provided methods to ablate prostate tissue while being minimally invasive. There is renewed interest in primary cryoablation, particularly as focal treatment for localized disease as well as salvage therapy, and high-intensity focused ultrasound (HIFU) appears promising. The ability to treat local disease within the prostate by these modalities may play a role even in men with locally advanced disease, most likely in combination with AD or other systemic therapy.

Cryoablation

Several series have been reported regarding primary cryoablation of the prostate and include many men with high-risk disease (Ahmed et al, 2009). Among 975 men undergoing cryoablation, 41% were high risk and 24% were stage cT3 in the report from Long and colleagues (2001). At a median follow-up of 24 months, the 5-year actuarial biochemical-free survival, defined as PSA less than 1 ng/mL, was 41%. A similar PSA outcome (35%) using the same definition was observed in another group of men with PSA 10 ng/mL or greater and/or Gleason sum 8 or higher undergoing primary cryoablation (Prepelica et al, 2005). However, use of more stringent PSA cutoff values may result in significantly worse outcomes, with 2-year rates of biochemical failure higher than 80% if thresholds of 0.5 or 0.2 ng/mL are applied (El Hayek et al, 2008). Chin and colleagues (2008) randomized men with clinical stage T2c-T3 disease to 6 months of AD and either cryoablation or RT at 66 Gy. At a mean follow-up of 37 months, there were no differences in disease-specific (95% to 97%) and overall (87%) survival, but cryoablation was associated with shorter PSA-free survival (28 months vs. 41 months) and higher biochemical failure (87% vs. 53%).

High-Intensity Focused Ultrasound

The role of HIFU continues to be elucidated, particularly in men with locally advanced prostate cancer. The limited existing data are confounded by frequent omission of risk stratification and common use of AD to reduce prostate size. At 1-year follow-up, 30 men with locally advanced or high-risk disease receiving AD plus HIFU had reasonable local control, with PSA less than 0.3 ng/mL and negative sextant biopsies in 90%; no patient had clinical disease progression (Ficarra et al, 2006). A larger series from Sumitomo and colleagues (2008) compared men receiving HIFU with and without NAD and without subsequent adjuvant therapy. In the 29% with high-risk cancers by D'Amico criteria, NAD reduced both positive biopsy rate and biochemical failure. Three-year disease-free survival was independently affected by stage cT2c or higher (HR 2.34) and lack of NAD (HR 2.19) in multivariable analysis. Parallel to studies of RT, outcomes of local treatment using HIFU may be improved when combined with NAD, primarily in men with intermediate- and high-risk disease characteristics.

ANDROGEN DEPRIVATION AND ITS TIMING

The VACURG and MRC trials suggest a benefit to early application of AD in men with locally advanced prostate cancer. The first VACURG study randomized 1050 patients with stage III disease and 853 patients with stage IV disease to placebo, 5 mg of DES, orchiectomy plus placebo, or orchiectomy plus 5 mg of DES. All three AD arms had significantly less progression than the placebo group had, but this did not translate into an overall survival benefit. The inability to demonstrate a survival benefit cannot be completely attributed to the increased cardiovascular deaths within the DES groups because survival in the orchiectomy plus placebo group was not significantly different from that in the placebo-alone group. The second VACURG study randomized 1506 men with stage III and stage IV disease to placebo or one of three doses of DES (0.2 mg, 1 mg, 5 mg). DES at 1 mg and 5 mg delayed progression of stage III disease, and patients receiving 1 mg had improved overall survival. However, the 5-mg dose of DES again resulted in increased cardiovascular death. Subsequent analysis suggested that immediate estrogen therapy was most beneficial in patients younger than 75 years with high-grade tumors (Gleason sum 7-10). The third VACURG study supported that only a subset of men with prostate cancer benefit from early AD. In men with stage II disease, 5-year survival was 48% with placebo and 75% with 1 mg of DES. Taken together, the VACURG data provide evidence of benefit for early AD with respect to disease progression and potential survival only in subsets of men with more aggressive disease (Byar, 1973; Byar and Corle, 1988). The studies also clearly show that alternatives to estrogen should be used, given the cardiovascular toxicity associated with higher doses of DES. The current ability to better monitor disease progression, with use of PSA kinetics and imaging modalities, may improve the outcomes of delayed AD by better determining when institution of AD is necessary.

The MRC also evaluated the issue of early versus delayed AD (orchiectomy or LHRH agonist) in 938 patients with prostate cancer, of whom 501 had locally advanced disease. The majority of deaths (67%) were attributed to prostate cancer. Cancer-specific mortality was 55% in the early AD group and 43% in the deferred group ($P = .001$). Overall survival was also improved in the immediate AD arm ($P = .02$). The reduction in prostate cancer death was primarily due to patients with M0 disease. This study also provides important data for comparison to other forms of treatment. Median time to death from prostate cancer (cT3M0) was 90 months, comparing favorably to EORTC 22863, in which median time was not reached after 65.7 months. Similarly, median overall survival in the MRC study was 64 months but not reached in EORTC 22864 (56.7 months of follow-up). Thus the apparent beneficial effects of combined AD and RT may be due in part to AD alone with uncertain incremental advantage of RT. The results from the Scandinavian Prostate Cancer Group Study 7/Swedish Association for Urological Oncology 3 (SPCG-7/SFUO-3) trial suggest an important role of RT, in addition to AD, in men with locally advanced disease (78% cT3) (Widmark et al, 2009). Men were randomized to either total AD followed by continuous flutamide or endocrine therapy combined with RT. At median follow-up of 7.6 years, both prostate cancer-specific and overall mortality were decreased in the group receiving AD plus RT (RR 0.44 and 0.68, respectively), and PSA recurrence was higher in men receiving AD alone (75%) compared with the RT group (26%). Despite limitations including the unconventional endocrine regimen and open study design, use of RT and potentially other local treatment modalities appears warranted in men with locally advanced prostate cancer. The MRC UK PR07 trial similarly compared AD only with AD and RT; in this study, patients had more advanced disease, AD was accomplished by either continuous LHRH agonist or orchiectomy, and pelvic nodes were treated with RT. The addition of RT to AD improved disease-specific (HR 0.54) and overall (HR 0.77) survival at 7 years (Warde et al, 2011).

Studer and colleagues (2004) evaluated the timing of AD in a study randomizing 197 asymptomatic men with prostate cancer to either immediate or deferred subcapsular orchiectomy; of note, patients were either unsuitable for or unwilling to undergo surgery

or RT. A significant fraction of the cohort had higher-risk features, with clinical stage T3 or higher in 67% and median serum PSA level above 46 ng/mL. Of the 92 men in the deferred treatment arm, 42% never required AD; the majority died of causes unrelated to prostate cancer. The median time to deferred AD was 3.2 years, the most common indication being skeletal metastases (45%) and ureteral obstruction (25%). Although overall survival was not different between the immediate and deferred groups ($P = .96$), a trend toward improved cancer-specific survival was noted in those men receiving immediate AD, with an HR for death from prostate cancer of 0.63 ($P = .09$).

To minimize adverse impact on quality of life, antiandrogen therapy alone has been proposed as an alternative to orchiectomy or LHRH agonists. Iversen and colleagues (2004) reported on the effects of 150 mg of bicalutamide in men with localized or locally advanced prostate cancer, the majority of whom were untreated initially (81%). At median 5.3 years of follow-up, survival in those with locally advanced disease was improved with bicalutamide compared with placebo (HR 0.68). Overall, risk of disease progression was reduced by 43%, with the greatest benefit in locally advanced tumors (HR 0.4). The combined analysis of the three Early Prostate Cancer bicalutamide trials ($n = 8113$) confirmed improved progression-free survival in the bicalutamide group (Wirth et al, 2004a). Overall survival was not different between the treatment and placebo arms in each trial, but men with locally advanced disease receiving bicalutamide alone (i.e., no surgery or RT) appeared to have improved survival. Although apparently promising in men with high-risk tumors, bicalutamide at 150 mg must be approached cautiously, both in men deferring local therapy and after definitive treatment. In analysis of the Early Prostate Cancer data (median follow-up of 5.4 years), men with localized prostate cancer receiving bicalutamide as primary therapy had an increased risk of death (HR 1.23, 95% CI 1.00 to 1.50) compared with surveillance alone. Immediate high-dose bicalutamide is not currently appropriate in men with low risk of disease progression, and potentially adverse effects should be sought in higher-risk patients with extended follow-up.

Wirth and colleagues (2004b) tested adjuvant flutamide (750 mg) after radical prostatectomy in men with pT3-T4N0 disease. Recurrence-free survival, defined as a single PSA value above 5 ng/mL or two PSA values above 2 ng/mL, was improved with flutamide (HR 0.51) at median follow-up of 6.1 years; however, overall survival was comparable (HR 1.04). Significant toxicity was associated with flutamide and accounted for nearly half of withdrawals from the treatment arm.

KEY POINTS: ANDROGEN DEPRIVATION

- Early androgen deprivation may improve survival.
- Alternative methods of androgen manipulation (antiandrogen, intermittent) remain investigational.

Intermittent Androgen Deprivation

Another approach to minimizing AD-related morbidity is the intermittent application of androgen suppression. Forty-nine patients (28 with cT3-T4N0M0 disease) were treated with total AD until the PSA level was less than 4.0 ng/mL between 24 and 32 weeks, after which treatment was withheld after 36 weeks (Sato et al, 2004). PSA level was then monitored and treatment was recommended when the PSA level reached either pretreatment level (when it was <15 ng/mL) or 15 ng/mL (when the initial PSA level was higher than that). During median follow-up of 126.1 weeks, mean time off treatment during cycles 1, 2, and 3 was 46.1, 36.9, and 23.3 weeks, respectively. No symptomatic or clinical disease was reported in the non-metastatic subgroup, and PSA failure was observed in 3 (11%) of these patients, with all patients alive at last evaluation. The optimal timing of intermittent AD for reduction of patient morbidity and

disease-specific end points remains to be determined, particularly in light of data from the trial of intermittent versus continuous AD in men with metastatic, hormone-sensitive prostate cancer (Hussain et al, 2013).

Quality of Life

The early institution of AD in men with prostate cancer, whether the cancer is localized or locally advanced, must be balanced against the known side effects and long-term morbidity. Only recently has the impact of AD on bone events, cognitive function, and quality of life been appreciated and reported. In comparing bicalutamide (150 mg) and castration with locally advanced but nonmetastatic disease, both sexual interest and physical capacity were better with bicalutamide monotherapy (Iversen et al, 2000). Although hot flashes were more common with castration, a trend toward reduced quality of life was associated with bicalutamide, including higher incidence of gynecomastia, breast pain, and asthenia. In the study of intermittent AD from Sato and colleagues (2004), many quality-of-life domains were improved during off-treatment cycles, including potency and social and family well-being.

The multimodal approach with AD and RT may increase the relative toxicity compared with each intervention alone. Schultheiss and colleagues (1997) reported that NAD was correlated with later gastrointestinal and genitourinary (grade 2 or higher) morbidity. Another study found that adjuvant AD after RT predicted for late grade 2 to grade 4 rectal toxicity (Sanguineti et al, 2002). Within RTOG 86-10, potency after RT with or without AD was similar at 81% and 74%, respectively. Chen and colleagues (2001) also found that the addition of AD did not further contribute to decline in sexual function after RT. Zelefsky and colleagues (1999) evaluated predictors of late toxicity in men treated with three-dimensional conformal radiotherapy. Although the 5-year actuarial likelihood of gastrointestinal and urinary toxicities was low (<10% overall), use of NAD was an independent predictor ($P = .01$) of post-treatment erectile dysfunction. The incidence of rectal morbidity and sexual dysfunction may be related to duration of AD longer than 6 or 9 months.

The benefits of adjuvant AD plus RT for locally advanced prostate cancer, both short and long term, appeared to outweigh the associated side effects in a number-needed-to-treat analysis (Jani et al, 2003). A model that compared treatment options while incorporating benefit and complications was constructed, and data from randomized trials of RT with or without AD for cT2c-T4N0-1 disease were input into the calculation. Even considering the increased incidence of side effects of long-term AD, this approach appeared to be better than short-term AD for virtually all end points evaluated.

Given concerns regarding AD and impact on body mass index, lipid profile, diabetes, and cardiovascular disease, Efstathiou and colleagues (2009) assessed the relationship between AD and cardiovascular events within RTOG 85-31. Adjuvant AD (median duration 4.2 years) was not associated with increased cardiovascular mortality. Additional evidence from RTOG 86-10 suggests that short-term NAD also does not increase the risk of fatal cardiac events.

MANAGEMENT OF DELAYED SEQUELAE

The direct comparison of prostatectomy and RT in the treatment of locally advanced prostate cancer is challenging and primarily based on historical studies. Even with the addition of neoadjuvant and adjuvant systemic therapy, leaving the prostate gland in situ poses potential problems. First, effective local control of some high-risk cancers may influence survival. Second, local recurrence may lead to the need for additional treatment of the prostate. At 10 years, local recurrence rates after RT for cT3 or stage C disease range from 24% to 74%. Holzman and colleagues (1991) reported that 36% of patients required transurethral resection of the prostate because of urinary obstruction after RT alone, without AD. Other morbidity included hydronephrosis (20%) and incontinence (13%). An older

report (Tomlinson et al, 1977) also demonstrated significant local complications of stage C prostate cancer with nonextirpative interventions—infection (80%), bladder outlet obstruction (75%), gross hematuria (45%), and ureteral obstruction (40%). Systemic therapy in the form of AD may not prevent local progression or reduce the need for palliative intervention. Despite orchiectomy for bladder outlet obstruction, 31% of men with locally advanced disease required transurethral prostate resection because of persistent voiding dysfunction after 60 days. Similarly, in 277 patients with cT2-T4 disease randomized to orchiectomy, RT, or both, rates of local disease control were comparable (Fellows et al, 1992). Studer and colleagues (2004) demonstrated that AD alone, whether it is instituted early or late, does not prevent local morbidity. More than half of the men in their study required transurethral resection of the prostate. In addition, delayed institution of AD was necessary because of ureteral obstruction (25%), anticipation of local complications (10%), and rectal infiltration (4%).

Quality of life is an increasingly important end point for prostate cancer. However, the impact of untreated local tumor progression or the various treatment modalities for locally advanced disease on quality-of-life outcomes is poorly characterized. Rosenfeld and colleagues (2004) examined the relationship between cancer stage and quality of life in 341 ambulatory men with prostate cancer. Instruments used included the Functional Assessment of Cancer Therapy (FACT), the urinary function subscale of the UCLA Prostate Cancer Index, and the Hospital Anxiety and Depression Scale (HADS). The stage of prostate cancer was significantly associated with most FACT subscales—increasing stage was negatively correlated with nearly every FACT subscale score; the observation persisted in multivariate models, accounting for covariables such as comorbidity and time since diagnosis. Interestingly, stage was more strongly associated with physical domains of health-related quality of life and there was no association with psychological symptoms as measured by HADS.

Berg and colleagues (2007) treated high-risk patients with RT monotherapy and characterized quality of life using validated instruments. Although mean scores for bowel function were similar to those for a normative control population, bowel bother and diarrhea were greater after RT. Patients who had clinical progression or required AD reported worse sexual, urinary, and social function and more sleeping problems and exhibited great declines in all domains over time. Data from CaPSURE (Wu et al, 2008) also suggest that men with high-risk cancer are likely to suffer negative effects beyond cancer outcomes. Use of AD with both surgery and RT was associated with a loss of sexual function that improved within 9 months, whereas the combination of external beam RT and brachytherapy resulted in continuous worsening of urinary function and bother.

Additional evidence from SWOG 8794 supports an adverse impact of multimodal therapy on quality of life (Moinpour et al, 2008). Men receiving adjuvant RT reported worse bowel and urinary function, but not erectile function, compared with surgery alone. Although symptom distress was significantly worse for the adjuvant RT group, likely correlating with bowel and urinary problems, there were no differences in other general measures of health-related quality of life, whereas global health-related quality of life was initially worse but continuously improved over time after adjuvant RT.

CLINICAL TRIALS

Given that outcomes of therapy are not optimal for those men with high-risk disease features, patients who present with such cancers should be considered for enrollment in novel clinical trials (<http://clinicaltrials.gov/>). Table 118-11 summarizes phase III clinical trials for high-risk or locally advanced prostate cancer; some of these have completed accrual and others are ongoing. The resulting data should answer some of the current questions regarding the optimal type and timing of traditional combination treatment, as well as the role of chemotherapy, in men with locally advanced and high-risk prostate cancer.

TABLE 118-11 Current and Pending Phase III Clinical Trials in Locally Advanced/High-Risk Prostate Cancer

STUDY	ELIGIBILITY CRITERIA	TREATMENTS
RADICAL PROSTATECTOMY		
Neoadjuvant		
CALGB 90203	Clinically localized, ≤60% 5-yr disease free, Gleason 8-10	Surgery alone vs. estramustine/docetaxel
Adjuvant		
SWOG 9921	Gleason 8-10, pT3b-4, PSA >20 ng/mL, N1, Gleason 7 and + margin	AD (2 yr) vs. AD + mitoxantrone/prednisone
VA Study 553	pT3b-4, pT3a and Gleason ≥7, pT2 and Gleason 8-10 and + margin, PSA >20 ng/mL	Surveillance vs. docetaxel/prednisone
SPCG 12	pT3a and Gleason ≥4+3, pT2 and + margin and Gleason ≥4+3, pT3b and Gleason ≥7	Surveillance vs. docetaxel
NCT 00667069	>pT2 or R1 N0/x and PSA ≤0.1 ng/mL	Immediate vs. delayed RT + triptorelin
MRC PR 10	After radical prostatectomy with PSA ≤0.2 ng/mL: pT3-4, Gleason 7-10, preoperative PSA ≥10 ng/mL, + margin	Immediate vs. delayed RT RT vs. RT + 6 mo AD vs. RT + 24 mo AD
EXTERNAL BEAM RADIATION THERAPY		
RTOG 0924	Gleason 7-10 and cT1c-2b and PSA <50 ng/mL, Gleason 6 and cT2c-4 or >50% biopsies and PSA <50 ng/mL, Gleason 6 and cT1c-2b and PSA >20 ng/mL	NAD + prostate/seminal vesicle RT + RT boost vs. NAD + whole-pelvic RT + RT boost
Neoadjuvant		
RTOG 9910	Gleason 2-6 and PSA 10-100 ng/mL, Gleason 7 and PSA <20 ng/mL, cT1 and Gleason 8-10 and PSA <20 ng/mL	8 wk NAD vs. 28 wk NAD
CAN-NCIC-PR12	≥T3a, Gleason ≥8, PSA >20 ng/mL	NAD + docetaxel vs. NAD
Adjuvant		
RTOG 9902	Gleason ≥7 and PSA 20-100 ng/mL, ≥cT2 and Gleason ≥8 and PSA <100 ng/mL	AD vs. AD + estramustine/etoposide/paclitaxel
NCT 116142	cT1-T2a and PSA <10 ng/mL or Gleason ≥4+3 or PSA velocity >2 ng/mL/yr, cT2c-4 and tertiary Gleason 5 or T3b or Gleason ≥3+4 with ≥50% cores positive	AD vs. AD + docetaxel
RTOG 0521	Gleason ≥9 and PSA ≤150 ng/mL, Gleason 8 and PSA <20 ng/mL and ≥cT2, Gleason 7 or 8 and PSA 20-150 ng/mL	AD vs. AD + docetaxel/prednisone
RTOG 1115	Gleason ≥9 and PSA ≤150 ng/mL and any T stage, Gleason 8 and PSA <20 ng/mL and ≥T2, Gleason 8 and PSA 20-150 ng/mL and any T stage, Gleason 7 and PSA 20-150 ng/mL and any T stage	AD (24 mo) + dose-escalated RT vs. AD (24 mo) + TAK-700 + dose-escalated RT
SPCG 13	cT2 and Gleason 4+3 and PSA 10-70 ng/mL, cT2 and Gleason 8-10 and PSA <70 ng/mL, cT3	AD vs. AD + docetaxel
ANDROGEN DEPRIVATION		
CAN-NCIC-PR3	cT3-4N0/M0, cT2 and PSA >40 ng/mL, cT2 and PSA >20 ng/mL and Gleason ≥ 8	AD alone vs. additional pelvic RT
NCT 00055731	Gleason >7, cT3-4, N1, PSA >20 ng/mL	AD vs. AD + docetaxel/estramustine

AD, androgen deprivation; NAD, neoadjuvant androgen deprivation; PSA, prostate-specific antigen; RT, radiation therapy.

Radical Prostatectomy

Radiation Therapy

Cryotherapy

High-Intensity Focused Ultrasound

Summary

RADICAL PROSTATECTOMY**Definition of Biochemical Recurrence after Radical Prostatectomy**

Radical prostatectomy is one of the most common treatment modalities for localized prostate cancer, and despite refinements in surgical technique and improved patient selection, approximately 25% to 41% of men will develop prostate-specific antigen (PSA) recurrence 10 years after surgery (Amling et al, 2000; Hull et al, 2002; Roehl et al, 2004). It is clear that not all men with a detectable PSA level after surgery are destined to clinical progression, defined as development of metastatic disease, need for second-line treatment, or death from prostate cancer. A significant portion of men will have a detectable PSA level that plateaus and does not progressively rise. Several hypotheses exist as to why this phenomenon occurs. First, residual benign disease is left in the prostatic bed (often used as the rationale for a detectable PSA level after radiation therapy). Second, PSA is produced at very low levels by cells of nonprostatic origin (Diamandis and Yu, 1995). Third, PSA elevation is a result of residual low-grade prostate cancer destined to follow an indolent course (Amling et al, 2001).

In the prostate cancer literature, specifically after radical prostatectomy, there are more than 50 separate definitions of biochemical recurrence (Zincke et al, 1994; Moul et al, 1996; Cookson et al, 2007). A standard definition of PSA recurrence is needed that accurately predicts for progression to clinically relevant end points such as metastatic disease, need for secondary treatments such as radiation therapy and androgen deprivation therapy (ADT), and death from prostate cancer. This must be tempered by the need for this same definition to identify patients at sufficiently low PSA levels (disease burden) to intervene with second-line therapies at a point in the disease course that will be meaningful. Several groups have examined various definitions of PSA recurrence that make sense for clinical practice and for standardization of therapy both for patient care and research purposes.

Stephenson and colleagues (2006a) reviewed the Memorial Sloan Kettering experience of 3125 patients who underwent radical prostatectomy. They found that after a median follow-up of 49 months, 75 men developed distant metastatic disease. Using a goodness-of-fit (R^2) statistic, they examined 10 candidate definitions of PSA failure for their predictability of metastatic progression. They determined that a PSA value of at least 0.4 ng/mL followed by another increase was the best fit for metastatic progression, as well as high predictability for secondary therapy, continued PSA progression, and rapid doubling time. Furthermore, Amling and colleagues

(2001) determined significance in using a definition of PSA level of 0.4 ng/mL or greater. At a value of 0.2 ng/mL, only 49% of men subsequently developed a further rise in PSA level compared to 72% of patients with a PSA value of 0.4 ng/mL or greater. Lost in a "standard" definition of PSA recurrence is clinical progression risk and how it relates to different definitions of failure. For example, a PSA value of 0.1 ng/mL may mean a different clinical outcome in a patient who had a radical prostatectomy 8 years earlier with pathologic Gleason 6 disease versus a patient who had surgery 6 months earlier for high-volume Gleason 9 prostate cancer. Mir and colleagues (2014) addressed this issue by examining 14 definitions of biochemical recurrence and how they relate to the probability of subsequent rise in PSA level, use of secondary treatment, or clinical progression. In the entire cohort, a single detectable PSA level, even at low levels (≤ 0.1 ng/mL), was associated with a subsequent rise in 30% to 55% of patients. In patients with high-risk features, a detectable PSA level was associated with a PSA progression probability of 73% to 88% compared to only 18% to 25% in patients with low-risk features. The optimal definition for patients with a 5-year progression-free probability of less than 50% (high-risk patients) was a single PSA value of 0.05 ng/mL or greater, and the ideal cut point in those with a progression-free probability greater than 90% (low-risk patients) was a PSA value 0.4 ng/mL or greater.

Because of the wide variation in definition of biochemical recurrence, the American Urological Association Prostate Guidelines Panel for Localized Prostate Cancer released their recommendations for reporting PSA recurrence in 2007. Their goals in a unifying definition were to determine an early marker of treatment failure in advance of clinical progression, use a low enough value to allow for patients to be candidates for early salvage therapy, and for a standard definition to be used as comparison among different patient series. The American Urological Association (AUA) guidelines panel ultimately defined PSA recurrence as a value of 0.2 ng/mL or greater with a second confirmatory laboratory value (Cookson et al, 2007). This also has been adopted by the European Guidelines on Prostate Cancer (Heidenreich et al, 2008).

Natural History of Biochemical Recurrence after Prostatectomy

Recurrence of PSA normally precedes clinically meaningful events in an extremely protracted and variable manner. In the seminal article describing the natural history of biochemical recurrence after radical prostatectomy, Pound and associates (1999) determined that the median actuarial time from biochemical recurrence to

metastasis was 8 years. Furthermore, the median actuarial time to death was 5 years, although this depended on the time from biochemical recurrence to metastasis, because patients who developed metastatic disease early had decreased median survival (Pound et al, 1999). In their initial analysis they determined that the risk for metastasis depended on time to biochemical recurrence, Gleason score, and PSA doubling time. In a recent update, metastasis-free survival was 10 years, potentially reflecting improvements in patient selection and management. Established factors that predicted for metastasis-free survival included Gleason score and PSA doubling time, but time to biochemical recurrence was not found to be significant in this cohort (Antonarakis et al, 2012). Using cut points of Gleason score (≤ 6 vs. 7 vs. 8 to 10) and PSA doubling time (< 3 vs. 3 to 8.9 vs. 9 to 14.9 vs. ≥ 15 months) was valuable to stratify patients into distinct risk groups.

Predictive models of prostate cancer–specific mortality after biochemical recurrence have been established. In a large cohort of 379 men who experienced biochemical failure, median survival after 16 years still had not been reached, demonstrating the potential for prolonged survival (Freedland et al, 2005). However, risk for metastasis and eventual death is extremely variable and risk factors need to be identified to predict those needing early aggressive therapy and enrollment into clinical trials. Data demonstrate that PSA doubling time, pathologic Gleason score, and time from surgery to biochemical recurrence are predictive of prostate cancer–specific mortality (Freedland et al, 2005, 2006). Using a cut point of 3 years, the actuarial 15-year survival differed from 41% for those with recurrence at less than 3 years after surgery versus 87% for those who had biochemical recurrence later than 3 years after radical prostatectomy (Freedland et al, 2006). In fact, for every year in delay from prostatectomy to biochemical recurrence, the prostate cancer–specific mortality risk decreases by 24% (Freedland et al, 2006). Conversely, in a series of men with biochemical recurrence not receiving either neoadjuvant or adjuvant therapy, Boorjian and colleagues (2011) found that time from prostatectomy to biochemical recurrence was not significantly associated with systemic progression (demonstrable metastases on radionuclide bone scan or on biopsies outside of the prostatic bed) or prostate cancer–specific mortality. They determined that age, Gleason score, advanced tumor stage, and rapid PSA doubling time were predictive of clinical progression.

The majority of men who experience biochemical recurrence after radical prostatectomy will not succumb to disease. However, risk factors for aggressive progression to clinically relevant disease and death are extremely important for patient counseling, clinical trials, and early implementation of salvage therapies. Using an established nomogram for prostate cancer recurrence (Kattan et al, 1998), Stephenson and colleagues (2009) demonstrated that 15-year prostate cancer–specific mortality was 5% in the most favorable quartile of PSA recurrence whereas patients in the least favorable 5-year PSA progression-free probability had a 15-year prostate cancer–specific mortality of 38%. Further, it is important to note that evaluation of PSA after prostatectomy should occur indefinitely because up to 27% of men will experience recurrence after 5 years and these patients are still at risk for clinical progression (Ward et al, 2003).

Prediction of Biochemical Recurrence after Prostatectomy

Regardless of the definition chosen for biochemical recurrence, it is clear that almost all clinical recurrences are preceded by a detectable and rising PSA level. Predicting patients who will have biochemical recurrence is important in terms of counseling, identifying those likely to need secondary therapy, and potentially treating with neoadjuvant treatments on clinical trials. Several groups have evaluated clinical and pathologic factors that may contribute to risk for biochemical recurrence. Using data from large operative series in men with prostate cancer, it has become clear that clinical factors can be used to predict for biochemical failure. Roehl and associates (2004) evaluated their series of 3478 men and determined after multivariable analysis that the most important factors for predicting for

biochemical recurrence were pretreatment PSA level, clinical stage, Gleason sum, pathologic stage, and era in which the radical prostatectomy was performed. Other groups have confirmed the importance of biopsy Gleason score; clinical tumor, node, metastasis (TNM) stage; and PSA level before therapy and Gleason score and tumor stage postoperatively as the largest covariates for biochemical recurrence prediction (Han et al, 2003).

A good surgical outcome after radical prostatectomy always has been the eradication of disease while maintaining continence and potency. To achieve the goal of cancer control, it always has been important to achieve negative surgical margins, because this is a predictor of biochemical failure (Stephenson et al, 2005). It has become clear that this is especially true when considering pathologic stage. Compared to a negative margin, men with positive margins in pT2 prostate cancer had a 12% increased risk for biochemical recurrence, whereas in pT3a and pT3b, the increased risk was 12% and 18%, respectively (Budaus et al, 2010). In fact, in this cohort of patients, those with pT3a and negative margins had a decreased risk for biochemical recurrence over that of those with pT2 cancer with positive margins. The length of positive margin also has been predictive of biochemical recurrence, because those with margins greater than 1 mm have a statistically significant increased risk for biochemical failure (Shikanov et al, 2009). Others have found that multiple positive margins as well as location of margin may be prognostically significant (Sofer et al, 2002; Stephenson et al, 2005). These data emphasize the importance of meticulous surgical dissection and appropriate surgical planning in patients who are likely to have advanced pathologic stage because positive surgical margins substantially worsen prognosis. Similarly, it has been shown that surgeon experience is predictive of outcomes. Surgeons who have performed more than 250 cases have a recurrence probability of 8.1% compared to 26.8% in those who have performed only 10 cases (Klein et al, 2008). Differences in experience may be partially explained by a difference in rate of positive margins between the more and less experienced surgeons.

In the age of evidence-based medicine and data-driven decisions, it is important to use objective data rather than “gestalt” when treating patients with prostate cancer. One of the most important predictive tools was created by Stephenson and colleagues (2006b) and published in 2006. Using the parameters of clinical stage, serum PSA value, Gleason score, and systematic biopsy results, this group created a prognostic tool for presurgery that has a concordance index of 0.76 to 0.79 for predicting for disease progression defined as serum PSA value of 0.4 ng/mL or greater and confirmed with a higher value, secondary therapy, clinical recurrence, or positive lymph nodes on frozen section during radical prostatectomy. Postoperatively, a similar tool using PSA, Gleason score, presence of extracapsular extension, seminal vesicle invasion, lymph node involvement, margin status, and adjuvant radiation can predict 10-year biochemical recurrence survival and has a concordance index of 0.79 to 0.81 (Stephenson et al, 2005). One important improvement/modification of this tool is that it calculates the 10-year progression-free probability based on the current disease-free interval already achieved. Nomograms have become popularized, are easily accessible, and are frequently used in patient counseling. The most commonly used nomograms accessible online are presented in Table 119-1.

Ultrasensitive Prostate-Specific Antigen

Traditionally, the lower limits of PSA detection have been in the range of less than 0.1 and 0.2 ng/mL. In the early 1990s, ultrasensitive PSA (uPSA) testing was introduced and has brought about increased sensitivity but also controversy. It is thought that early second-line treatment in patients destined for clinical failure portends improved survival. However, this is tempered by the risk of overtreating those patients who may never experience clinical failure despite continuous detectable values of extremely low PSA. Hong and associates (2010) demonstrated the utility of the uPSA in predicting biochemical recurrence defined as two consecutive rises in PSA level of 0.2 ng/mL or greater. On multivariate analysis, they

found that an undetectable uPSA along with preoperative PSA level, pathologic stage, and pathologic Gleason score were all significant predictors of biochemical failure. Patients with a nadir PSA level of less than 0.001 had a 3-year biochemical recurrence-free survival of 95.5% compared to 41.5% for those with a nadir PSA level of 0.05 or greater (Hong et al, 2010). These findings were confirmed by Shen and coworkers (2005), who determined PSA relapse (two consecutive PSA levels of ≥ 0.1 ng/mL or greater) in those with PSA nadir of less than 0.01 was 4% compared to 89% for those with nadir of 0.04 or greater.

Ultrasensitive PSA has demonstrated clinical utility in several scenarios. For instance, patients with undetectable uPSA at 2 years have been found to be unlikely to develop PSA doubling time less than 9 months (defined as a high-risk recurrence) after biochemical failure (Chang et al, 2010). In fact, for every month without a detectable uPSA, the odds for high-risk recurrence were decreased by 4%. Furthermore, the uPSA value at 3 years after radical prostatectomy is also predictive of eventual biochemical failure, because patients with a PSA level between 0.04 and 0.1 have a 10.8 times greater likelihood of developing eventual biochemical recurrence compared to those with PSA level of 0.04 or less (Malik et al, 2011). This is clinically relevant because patients who are free of disease at the 3-year mark can be counseled about their low probability of ever developing clinically relevant recurrence, which may ease some anxiety. Even after controlling for risk factors, uPSA nadir seems to be effective in predicting biochemical recurrence. Patients with pathologic T3 prostate cancer with undetectable uPSA have a 5-year biochemical recurrence-free survival of 78% compared to 40% for those who have a detectable uPSA level (Eisenberg et al, 2010). Interestingly, in patients with low-risk disease, the difference between patients with undetectable versus detectable uPSA was only 91% versus 89%, respectively, arguing that perhaps the significance of testing may lie in patients with intermediate- and high-risk cancer.

The enthusiasm for uPSA has been lessened by questions of clinical utility. Clearly, not all patients who develop detectable uPSA are destined for “traditional” biochemical recurrence. In fact, using a cutoff of 0.05 ng/mL, Eisenberg and colleagues (2010) found that approximately two thirds of their study cohort who attained this level did not progress to biochemical failure at 5 years. Others have pointed out the significant variability of the “background noise” at

values of PSA in the ultrasensitive range and further questioned its clinical utility (Taylor et al, 2006). PSA doubling time is established as an important prognostic indicator of clinical failure after radical prostatectomy. What has not been established is whether the calculated PSA doubling time using uPSA is relevant to this end. Reese and associates (2011) from the University of California–San Francisco determined that uPSA calculated doubling times have poor agreement with standard PSA doubling time using traditional values and that typically the value with uPSA was artificially shorter. Therefore the usefulness of uPSA in deciding on secondary therapy is limited.

Imaging in Patients with Biochemical Recurrence after Radical Prostatectomy

Patients who experience biochemical recurrence after definitive radical prostatectomy are at risk for both local recurrence and distant failure. Identifying patients with local failure only is critical to initiate salvage therapies while sparing those with distant metastatic disease the burden of local salvage therapy. Traditionally, imaging techniques have been limited in the diagnosis of recurrence when PSA levels have been low. For instance, the routine use of bone scans in patients with PSA levels less than 10 ng/mL is of limited value because only 4% will demonstrate a positive scan (Dotan et al, 2005). Similarly, traditional computed tomography (CT) is unlikely to be positive in patients with PSA levels less than 10 ng/mL (Okotie et al, 2004). Conversely, transrectal ultrasound (TRUS) has demonstrated reasonable sensitivity at low PSA levels, especially with masses at the vesicourethral anastomosis. Scattoni and colleagues (2003) demonstrate that TRUS followed by biopsy was positive in 45% of patients with a PSA level of 0.5 ng/mL or less and had 100% sensitivity in patients with a PSA level of 2.0 ng/mL or greater.

Indium-111 capromab pentetide scanning (ProstaScint; Cytogen, Princeton, NJ) incorporates an immunoglobulin G monoclonal antibody that binds to prostate-specific membrane antigen (PSMA). Its use in patients with biochemical recurrence has been limited because sensitivities and specificities are approximately 60% to 70% (Apolo et al, 2008). Further limiting the clinical adoption of ProstaScint is that the monoclonal antibody has been found to bind to

intracellular domains exposed only at apoptosis or necrosis (Troyer et al, 1997). Newer generation antibodies such as J591, which are more specific to the external components of PSMA, are promising for both prostate cancer detection and potential therapy (Smith-Jones et al, 2003).

Positron emission tomography (PET)/CT scan has gained popularity in the recurrent prostate cancer population. Although the use of ^{18}F -fluoro-2-deoxy-D-glucose (FDG) has been limited by low sensitivity secondary to modest glucose consumption in prostate cancer cells, similar uptake in benign tissue or postoperative scar, and high urinary excretion limiting anatomic delineation, radiotracers such as acetate, choline, and fluorocholine have demonstrated promise (Martino et al, 2011). In fact, the U.S. Food and Drug Administration approved choline PET for the detection of prostate cancer recurrence, which has demonstrated improvement over FDG/PET scans (Picchio et al, 2003). Two radiotracers for choline have been studied with similar results; however, ^{11}C -choline has the advantage of low urinary excretion and quality pelvic imaging. Conversely, ^{18}F -choline demonstrates higher urinary excretion but has a longer half-life and makes it suitable for centers without a cyclotron (Picchio et al, 2011). The validity of choline PET has been seen at PSA levels below 2.5 ng/mL, because up to 90% of patients will demonstrate positive scans with a specificity of 50% (Rinnab et al, 2007). Similarly, approximately 50% of patients with PSA levels less than 5.0 ng/mL were found to have a positive focus using ^{18}F -fluorocholine PET/CT. Unfortunately, PET scan with choline may be limited in patients with very low levels of PSA recurrence, because only half will be positive in patients with PSA levels less than 1.0 ng/mL (Vees et al, 2007). Another study demonstrated positive scans in only 5% of patients with PSA levels less than 1.0 ng/mL and 15% in patients with PSA levels of 1.0 to 2.0 ng/mL (Giovacchini et al, 2010).

C^{11} -acetate PET scans are another modality gaining favor in the evaluation of recurrent PSA after radical prostatectomy, with sensitivity as high as 75% in 20 men with a median PSA level of 2.0 ng/mL (Sandblom et al, 2006). Almeida and colleagues (2012) found an overall detection rate of recurrent or metastatic disease using C^{11} -acetate PET/CT of 85%. Patients with PSA values of 0.4 to 1.0 ng/mL had a detection rate of 73%, and patients with PSA levels greater than 2.0 ng/mL had a detection rate of 93% (Fig. 119-1).

PET/CT has demonstrated promise in the detection of prostate cancer recurrence; however, its clinical utility is still questionable because salvage therapies are most effective at lower levels of PSA and awaiting the conversion of PET scans to positive may delay potential curative therapy.

Magnetic resonance imaging (MRI) can be used in the detection of local recurrence after biochemical failure. Sella and colleagues (2004) analyzed endorectal MRI in 48 patients with biochemical failure after radical prostatectomy and found sensitivity and specificity of 95% and 100%, respectively. Lesions were isointense to muscle on T1-weighted images and slightly hyperintense to muscle on T2-weighted images. The mean PSA value before imaging was 2.18 ng/mL but included 25 (64%) patients with PSA levels below 1.5 ng/mL. The addition of dynamic contrast enhancement (DCE) has demonstrated an increase in accuracy over standard MRI with sensitivity of 88%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 88%. This was despite lower PSA values (mean 1.9 ng/mL) (Casciani et al, 2008). Furthermore, the combination of DCE and magnetic resonance spectroscopic imaging has demonstrated sensitivities as high as 86% in patients with PSA levels in the range of 0.4 to 1.4 ng/mL range (Sciarra et al, 2008). Compared to PET/CT, multiparametric MRI performs better in identification of local recurrence, especially at low levels of biochemical failure (Panebianco et al, 2012).

Salvage Radiation Therapy

The state of a persistent or rising PSA level after radical prostatectomy is challenging for patients and clinicians alike. Despite surgical management in patients with clinically localized prostate cancer, up to 40% of men will continue to harbor or develop a detectable PSA level (Amling et al, 2000; Han et al, 2001; Hull et al, 2002; Roehl et al, 2004; Ward and Moul, 2005). Current limitations in imaging modalities to identify local versus metastatic disease, especially at low PSA levels, create a treatment dilemma for clinicians. Despite ADT being a noncurative treatment for a rising PSA value after radical prostatectomy, approximately 60% of patients will undergo ADT as second-line treatment (Agarwal et al, 2008). Salvage radiation therapy remains the clearest choice and best chance for long-term freedom from progression.

Figure 119-1. C^{11} -Acetate positron emission tomography scan in biochemical recurrence.

In 2004 a large multi-institutional group published the results of salvage radiation therapy in 501 patients who had a detectable or rising PSA level after radical prostatectomy (Stephenson et al, 2004b). Four-year freedom from progression was 45% despite including a significant portion of patients with high-risk features thought to predict for metastatic disease (high-grade disease and rapid PSA doubling time) (Stephenson et al, 2004b). On multivariable analysis, Gleason grade, pretreatment PSA level, PSA doubling time, surgical margins, use of ADT, and lymph node metastasis were significant for predicting probability of disease progression (Stephenson et al, 2007). Other groups have demonstrated similar 5-year biochemical recurrence-free survival in 35% to 46% of patients treated with salvage radiation (Buskirk et al, 2006; Bastide et al, 2010; Geinitz et al, 2012). Boorjian and associates (2009) demonstrated in their series of 856 men who received salvage radiation therapy that 534 (63.6%) achieved an undetectable PSA after therapy. On multivariable analysis, patients who received salvage radiation were at a 90% decreased risk for local recurrence, 20% decreased risk for late administration of ADT, and a 75% decreased risk for systemic progression.

Although several groups have demonstrated the value of salvage radiation therapy in improving biochemical end points, Trock and colleagues (2008) reported that salvage radiotherapy, compared to observation, also improved prostate cancer-specific survival. They found a threefold increase in prostate cancer-specific survival with salvage radiation compared to observation. This was identified in patients who received therapy within 2 years of biochemical recurrence and with a PSA doubling time of less than 6 months (Trock et al, 2008). Furthermore, salvage radiation has been demonstrated to improve all-cause mortality (Cotter et al, 2011).

Failure after salvage radiation therapy can be due to persistent local disease, recurrence of local disease, persistence of metastasis, or development of metastatic disease. It is important to identify factors that may predict for failure after salvage therapy for patient counseling and surveillance. Several groups have performed analyses on their patient cohorts undergoing salvage radiation and have identified risk factors for predicting success or failure. Buskirk and associates (2006) identified on multivariable analysis that pathologic stage T3a or less versus T3b, pathologic Gleason score, and presalvage radiation PSA levels were all predictive of biochemical relapse. Further, using these factors, a scoring system was created so that patients with no or one adverse feature had a 5-year freedom from biochemical failure rate of 69% compared to 6% in those with four or five adverse features (Buskirk et al, 2006). In addition, patients with a PSA nadir greater than 0.05 ng/mL after salvage radiation therapy have an increased risk for distant metastatic disease and worsened prostate cancer-specific survival (Geinitz et al, 2012). Using a large multi-institutional cohort of 1540 men, Stephenson and colleagues (2007) created a nomogram that predicts outcomes after salvage radiation therapy. PSA level before salvage radiation, pathologic Gleason score, PSA doubling time, margin status, lymph node status, and ADT were included for the nomogram and had a concordance index of 0.69. Although the overall progression-free survival was only 32% in the entire cohort, those with PSA levels before therapy of 0.5 ng/mL or lower had a progression-free survival of 48% (Stephenson et al, 2007). Interestingly, patients with high-risk features such as PSA doubling time less than 10 months or Gleason score of 8 to 10 had reasonable 6-year progression-free survival of 41% (Stephenson et al, 2007). Furthermore, time to biochemical failure has been found to predict for development of distant metastatic disease, prostate cancer-specific mortality, and overall mortality (Johnson et al, 2013).

Dose Response with Salvage Radiation Therapy

The primary treatment of prostate cancer with radiation therapy has taught us that higher dosages of treatment led to improved prostate cancer outcomes with limited side effects (Zietman et al, 2005). Using the same logic, many groups have developed protocols of salvage therapy, enhancing both the dosages administered and the planned targeting using intensity-modulated radiotherapy (IMRT)

versus conformal therapy, which was administered in older cohorts (Buskirk et al, 2006; Geinitz et al, 2012). In 1999 the American Society for Therapeutic Radiology and Oncology Consensus Panel released recommendations on salvage radiation stating that dosages of at least 64 Gy should be administered to the prostatic bed (Cox et al, 1999). The dosage recommendations have been reaffirmed in the recent AUA guidelines for adjuvant and salvage radiation therapy (Thompson et al, 2013). However, emerging evidence now demonstrates improvement with higher dosages.

De Meerleer and coworkers (2008) published their results with a planned target volume of 75 Gy in 37 fractions and demonstrated a biochemical freedom from disease of 67% at 5 years. There were no acute grade 3 gastrointestinal (GI) toxicities and only 3% genitourinary (GU) toxicities. Accordingly, there were minimal late GI or GU toxicities on further follow-up. Gleason score at radical prostatectomy, perineural invasion, and capsular perforation of disease were all significant predictors of biochemical recurrence. When stratifying patients into groups based on dosages of radiation of low (<64.8 Gy), moderate (64.8 to 66.6 Gy), and high (>66.6 Gy), the estimated cumulative rate of biochemical failure at 5 years was 57%, 46%, and 39%, respectively (Bernard et al, 2010). Most recently, Ost and others (2011b) demonstrated that using a median dosage of 76 Gy, they achieved 5-year biochemical recurrence-free survival of 56% and clinical recurrence-free survival of 86%. This was achieved while keeping toxicity rates low, with total GU grade 2 and 3 toxicities of 22% and GI grade 2 and 3 toxicities of 8%. Modern series of radiation therapy along with recent meta-analyses suggest improved cancer control with higher dosages of treatment (King, 2012; Ohri et al, 2012). Despite these findings, clinicians must temper some of the enthusiasm based on the potential for increased treatment-related morbidity. Results of the SAKK 09/10 trial examining 64 versus 70 Gy in salvage radiotherapy will eventually shed light on dose escalation in this particular treatment setting (<http://ClinicalTrials.gov>, 2015).

Concurrent Androgen Deprivation Therapy with Salvage Radiation

Theoretically, the use of systemic therapy with androgen deprivation may sterilize micrometastatic disease, shrink tumor burden making it more amenable to local salvage therapy, and potentially work in synergy with radiation therapy to treat remaining cancer cells. However, the concurrent administration of ADT with salvage radical prostatectomy is controversial, with mixed results in multiple series. In a cohort of 635 men with biochemical and/or local recurrence, the addition of hormonal therapy in addition to radiation therapy did not result in improved prostate cancer-specific survival (Trock et al, 2008). Prostate cancer-specific survival of 5 and 10 years was 0.96 and 0.86 for radiation alone and 0.96 and 0.82 for radiation in addition to hormonal therapy (Trock et al, 2008). This was further confirmed in a study of high-dose radiation therapy in which concurrent androgen deprivation did not improve biochemical recurrence. Patients were given 6 to 9 months of ADT in those with perineural invasion, seminal vesical involvement, and Gleason score of 8 to 10, which may have introduced a selection bias (De Meerleer et al, 2008). Conversely, Stephenson and associates (2007) determined that ADT with a mean duration of 4.1 months before or during radiation therapy led to improvement in progression-free probability. However, the administration of ADT was not standardized and some patients received as little as 1 month versus 24 months (Stephenson et al, 2007). In a modern series of high-dose salvage IMRT, the addition of ADT for 6 months improved biochemical recurrence-free survival with a hazard ratio of 0.33 (Ost et al, 2011b). Perhaps not all patients with biochemical relapse after radical prostatectomy may benefit from concurrent ADT. Soto and coworkers (2012) from the University of Michigan examined their results with salvage therapy and concurrent androgen deprivation after risk stratification. In the entire cohort, multivariable analysis demonstrated that concurrent ADT, Gleason score, and pre-radiation therapy PSA level were all predictors of progression-free

survival. On risk stratification, they determined that only the patients in the high-risk group (pT3 or greater, Gleason score of 8 or greater, or PSA level of 20 ng/mL or greater) benefited from the addition of androgen deprivation (Soto et al, 2012).

To date, the only randomized controlled trial examining this clinical question is the Radiation Therapy Oncology Group (RTOG) 96-01. This is a trial comparing salvage radiation therapy with and without 2 years of bicalutamide therapy for patients with pT3N0M0 and pT2 with positive margins. Although the primary end point is overall survival, an interim analysis has been presented in abstract form representing 771 patients with a median follow-up of 7.1 years. Patients who underwent bicalutamide in addition to salvage radiation had a freedom from biochemical progression of 57% compared to 40% in patients who underwent radiation therapy alone. Furthermore, patients who had the combination therapy had a rate of distant metastasis of 7.4% compared to 12.6% in the radiation alone arm (Shipley et al, 2011). Although we must wait until the final analysis with overall survival, these results are encouraging. The Radiotherapy and Androgen Deprivation in Combination after Local Surgery (RADICALS) trial is a randomized phase III controlled trial that evaluated the timing of radiotherapy (adjuvant vs. early salvage) and the duration of concurrent ADT. Patients will receive none, 6 months, or 2 years of androgen deprivation with a gonadotropin-releasing hormone analogue or bicalutamide. The outcomes evaluated are cause-specific and overall survival (Parker et al, 2007). Final results of these trials will determine the necessity and optimal duration of ADT.

Whole-Pelvis versus Prostatic Bed Radiation Therapy

Very few series evaluate the role of whole-pelvis versus prostatic bed-only salvage radiation therapy after biochemical recurrence. Just like radiation dosage and concomitant ADT, there are no mature randomized controlled trials that clearly demonstrate the added benefit of whole-pelvis radiation. Spiotto and colleagues (2007) evaluated their experience in 160 men who underwent both adjuvant and salvage radiation therapy, of which 114 were considered high-risk for lymph node involvement (Gleason score ≥ 8 , preoperative PSA > 20 ng/mL, seminal vesicle involvement, capsular extension, and lymph node positivity). Seventy-two patients received whole-pelvis radiation versus 42 who underwent radiation of only the prostatic bed. The benefit of whole-pelvis radiation was limited to those with high-risk features with 5-year biochemical

recurrence-free survival of 47% versus 21% for prostatic bed alone (Spiotto et al, 2007). On multivariable analysis, whole-pelvis radiation and preoperative PSA level of less than 1 ng/mL were predictors of biochemical recurrence-free survival (Spiotto et al, 2007). Furthermore, in patients with high-risk features, concurrent androgen deprivation with whole-pelvis radiation conferred improved recurrence-free survival (Spiotto et al, 2007).

In 2013, Moghanaki and colleagues published their series of 247 patients undergoing salvage radiation therapy. This study compared two separate institutions with differing approaches to salvage radiation, with one group performing prostatic bed radiation (135 patients) and the other group performing pelvic nodal radiation in addition to prostatic bed (112 patients). Pretreatment PSA values and pathologic Gleason score were independent predictors of biochemical recurrence, but whole-pelvis radiation was not an independent predictor associated with PSA recurrence-free survival. Even after separating patients by low-risk and high-risk features, there was no benefit to whole-pelvis irradiation. However, when examining a subset of patients with preradiation PSA levels of 0.4 ng/mL or greater, there was a 53% risk reduction in biochemical progression with whole-pelvis radiation (Moghanaki et al, 2013).

RTOG 0534 is a randomized controlled trial currently accruing patients with high-risk prostate cancer features on radical prostatectomy and with postsurgery PSA levels of 0.1 ng/mL or greater to less than 2.0 ng/mL. Patients will be stratified by seminal vesicle involvement, Gleason score, pretreatment PSA level, and stage. Patients will be randomized to prostatic bed radiation alone, prostatic bed radiation plus 6 months of androgen deprivation, and prostatic bed radiation therapy plus pelvic lymph node radiation therapy along with 6 months of ADT. Patients will undergo either three-dimensional conformal radiotherapy (3D-CRT) or IMRT at 64.8 to 70.2 Gy for the prostatic bed and 45 Gy to the pelvic lymph nodes. The primary objective is to evaluate freedom from biochemical progression, clinical failure, and overall survival. The results of this trial will help clarify this treatment dilemma (Figs. 119-2 and 119-3).

Adjuvant Radiation Therapy

The National Cancer Institute defines adjuvant therapy as additional cancer treatment given after the primary treatment to lower the risk that the cancer will come back. Adjuvant therapy may include chemotherapy, radiation therapy, hormone therapy,

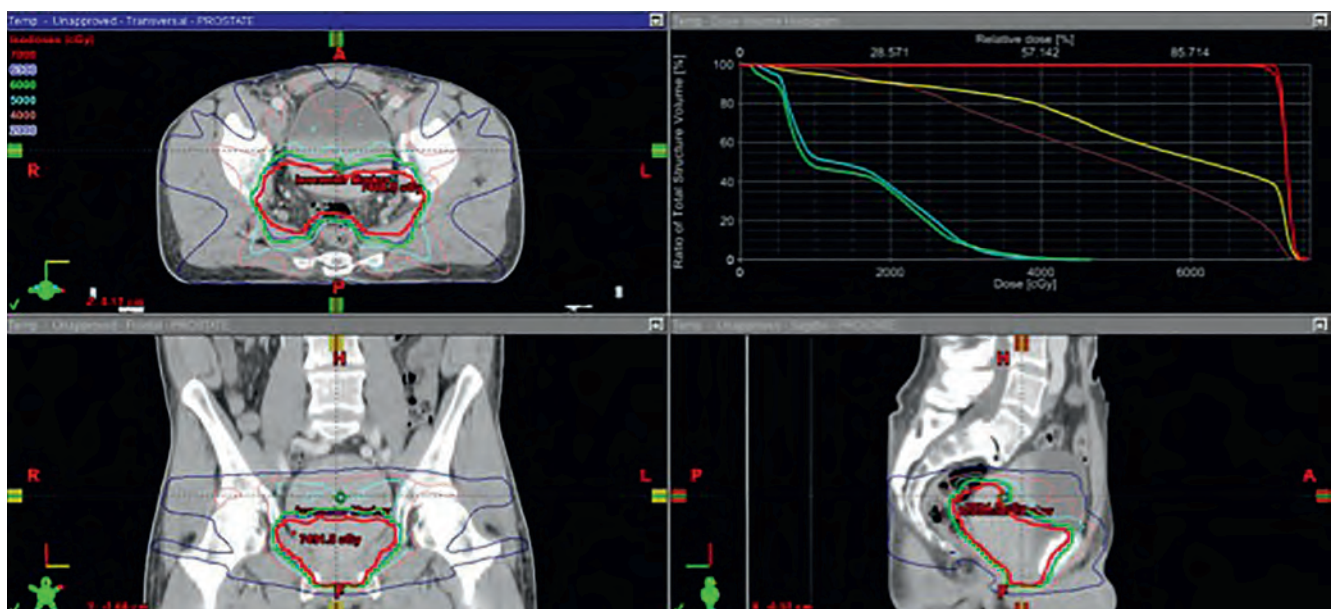

Figure 119-2. Prostate bed-only salvage radiotherapy after radical prostatectomy.

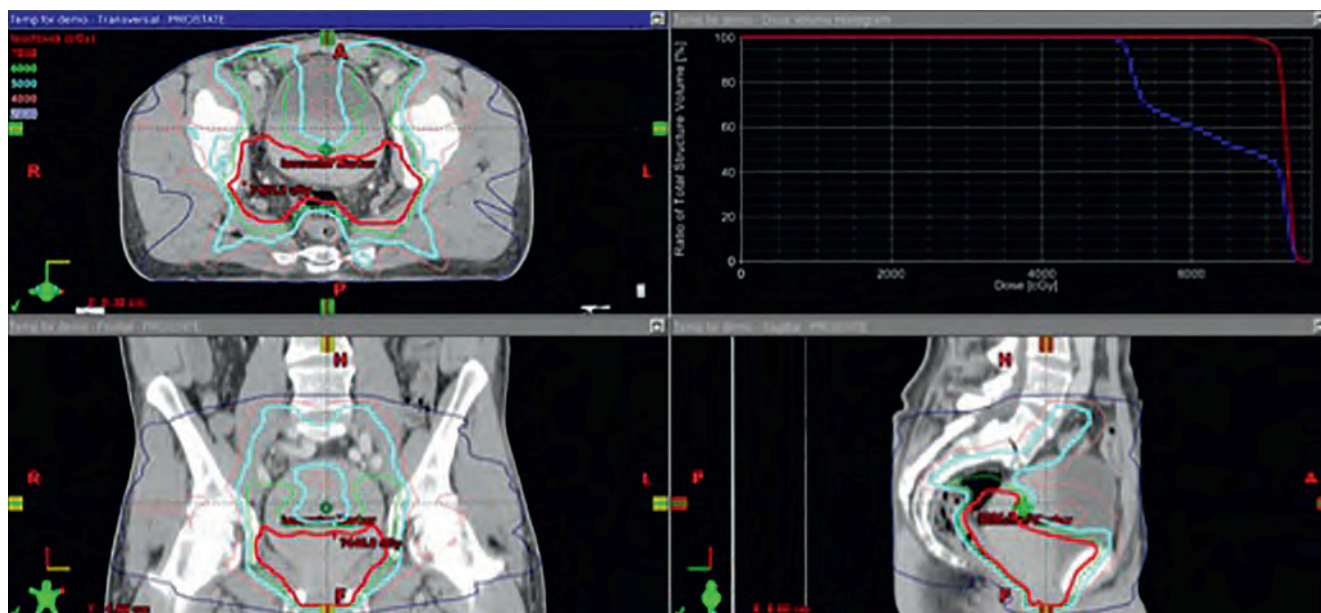

Figure 119-3. Whole-pelvis radiotherapy after radical prostatectomy.

targeted therapy, or biologic therapy (National Cancer Institute, 2015). After radical prostatectomy, patients at high risk for local recurrence are offered radiation therapy to prolong the disease-free interval. Typically, this is administered 4 to 6 months after radical prostatectomy when the PSA is still undetectable and when patients have regained urinary continence. Several well-performed, randomized clinical trials have demonstrated improved biochemical recurrence-free and cancer-specific survival with the implementation of adjuvant radiation therapy (Bolla et al, 2005; Thompson et al, 2006; Wiegel et al, 2009). In fact, the most recent AUA guidelines read, "Physicians should offer adjuvant radiotherapy to patients with adverse pathologic findings at prostatectomy including seminal vesicle invasion, positive surgical margins, or extraprostatic extension because of demonstrated reductions in biochemical recurrence, local recurrence, and clinical progression" (Thompson et al, 2013).

Southwest Oncology Group (SWOG) 8794 was initiated in 1987 and included 431 men with pT3 prostate cancer and/or positive surgical margins (Thompson et al, 2006). Patients were randomized into observation versus adjuvant radiation with 60 to 64 Gy in 30 to 32 fractions. Approximately two thirds of all participants had undetectable PSA at randomization (Thompson et al, 2006). At a median follow-up of approximately 12.5 months, the median metastasis-free survival in the adjuvant radiation therapy arm was 14.7 years compared to 12.9 years in the control group, which reached statistical significance (Thompson et al, 2009). Furthermore, the median overall survival was 15.2 years for the adjuvant therapy group compared to 13.3 years in the wait and see arm, again reaching statistical significance. The number of men with pathologic T3 disease who must be treated with adjuvant radiotherapy to prevent 1 death at a median follow-up of 12.6 years was 9.1 patients (Thompson et al, 2009). Therefore the authors conclude that adjuvant radiotherapy within 18 weeks after radical prostatectomy in a man with T3N0M0 prostate cancer significantly reduces the risk for PSA recurrence, metastasis, and need for hormonal therapy and increases overall survival (Thompson et al, 2009).

The European Organization for Research and Treatment of Cancer (EORTC) 22911 trial was initiated in 1992 and evaluated the role of postoperative radiotherapy after radical prostatectomy to a wait and see approach (Bolla et al, 2005). A total of 1005 patients were eventually randomized to either a wait and see approach or adjuvant radiation with 60 Gy. The primary end points included biochemical progression-free survival, clinical progression-free

survival, and local recurrence; however, during the trial, biochemical progression-free survival replaced local control as the primary end point. Kaplan-Meier estimated 5-year biochemical progression-free survival rate was 52.6% in the wait and see arm compared to 74% in the adjuvant radiation arm. Clinical progression-free survival, defined as no evidence of clinical, sonographic, radiographic, or scintigraphic recurrence, was also improved in the radiation group compared to the control group, as was locoregional failure at 5 years, which was significantly lower in the postirradiation group and 5.4% versus 15.4% in the wait and see group. There was no difference in overall survival (Bolla et al, 2005).

Finally, ARO 96-02, a German study, was published in 2009. Similarly to the other two phase III randomized controlled clinical trials, this was a comparison between adjuvant radiotherapy after radical prostatectomy and radical prostatectomy alone. A major difference in this trial from the other two is that patients had an undetectable PSA level after radical prostatectomy before randomization. A group of 388 patients with pT3 or pT4 but without nodal metastatic disease were randomly assigned after prostatectomy. Patients were included with and without positive margins. After exclusion of men for various reasons, 154 in the wait and see group and 114 in the adjuvant radiation group remained for final analysis. Radiation was delivered 6 to 12 weeks postoperatively when no voiding problems were present. Dose given was 60 Gy over 30 fractions from the seminal vesicle region to the apex, with some added security margin. Patients in the wait and see group underwent salvage therapy with radiation and/or hormone therapy on recurrence. The 5-year biochemical-free survival in the radiotherapy group was 72% versus 54% in the wait and see group (Wiegel et al, 2009).

Despite the well-performed phase III randomized controlled trials and the recent AUA guidelines, there exists some skepticism in regard to the optimal timing and necessity of adjuvant radiation. Opponents of pure adjuvant therapy argue that there is a risk for overtreating patients who are never destined to fail local treatment. In fact, a significant proportion of men with extracapsular extension, positive surgical margins, and/or seminal vesicle invasion at radical prostatectomy will not experience biochemical relapse (Eggerer et al, 2005; Swindle et al, 2005; Vis et al, 2006). Furthermore, there are significant local toxicities inherent to radiation therapy and patients should be counseled that treatment is not without consequence. In the SWOG study, there was a 3.2% rate of proctitis and bleeding, 6.5% rate of urethral stricture, and 17% rate

of total urinary incontinence, and there was a 4.2% rate of grade 3 or worse toxicities in the adjuvant radiation arm of the EORTC trial (Bolla et al, 2005; Thompson et al, 2006, 2009). Clearly, clinicians watching patients as they regain continence are hesitant to administer radiation doses that may at best halt urinary recovery and perhaps even worsen symptoms. However, with modern radiation targeting, accurate delivery of dosages may improve side effects. Further, increased doses of up to 70 Gy may improve long-term cancer outcomes and offset the deficits in quality-of-life outcomes associated with radiation therapy.

Subgroup analyses may indicate there are patient groups that may or may not benefit the most from adjuvant radiation. Van der Kwast and colleagues (2007) evaluated the results of a centralized review of the patients from the EORTC trial. Of the 1005 prostates, 552 were reviewed again, and only patients with a positive margin were found to have benefited from adjuvant radiation (Van der Kwast et al, 2007). The authors of ARO 96-02 also performed subgroup analysis and demonstrated that adjuvant radiation is favored in patients with positive surgical margins, PSA greater than 10 ng/mL, pT3a/b, and both Gleason stratifications (Wiegel et al, 2009). Finally, in the SWOG trial with the longest follow-up with the most clinically relevant end points of metastasis-free and overall survival, there was not a defined subgroup that did not benefit from adjuvant radiation (Thompson et al, 2009). Therefore, in adherence to the AUA guidelines, all men who are anticipated to have high-risk outcomes after radical prostatectomy should be counseled on the potential need for secondary treatment. After radical prostatectomy, all men with extracapsular extension, involved seminal vesicles, and/or positive margins should be counseled about the potential benefits of adjuvant radiation therapy.

Salvage versus Adjuvant Radiation Therapy for Prostate Cancer

Mature randomized controlled trials are lacking to evaluate salvage versus adjuvant radiation therapy. Several studies have compared the two, but there are inherent biases because patient cohorts who undergo salvage therapy already have demonstrated failure after radical prostatectomy whereas the adjuvant cohorts include up to 50% of patients who will not experience clinical progression. In a cohort of 192 men matched 1:1 by preoperative PSA levels, Gleason score, seminal vesicle invasion, and surgical margin, 5-year freedom from biochemical failure was 75% for adjuvant radiation versus 66% for salvage therapy. When examined from the end of radiation therapy, this was more significant, with 73% for adjuvant radiation versus 50% for salvage therapy (Trabulsi et al, 2008). This was despite a reasonable median presalvage radiation PSA level of 0.7. These findings were confirmed in a study of 219 patients subdivided into homogeneous subgroups based on lymphatic invasion and surgical margins in which they determined that adjuvant radiation in patients with high-risk features was associated with improved disease-free survival compared to salvage therapy (Budiharto et al, 2010). Furthermore, despite high-dose IMRT (74 to 76 Gy), adjuvant radiation therapy improved 3-year biochemical recurrence-free survival 90% versus 65% in salvage therapy (Ost et al, 2011a). Adjuvant therapy also demonstrated improvement in clinical progression-free survival. However, in subgroup analysis, early salvage therapy defined as delivery of radiation at a PSA level of 0.5 ng/mL or less demonstrated a 3-year biochemical recurrence-free survival of 86% compared to 46% for late treatment. The early group was comparable to 92% demonstrated by the adjuvant group ($P = .67$), demonstrating the potential role of early salvage radiation, which may spare the morbidity of radiation therapy to those patients who do not demonstrate a propensity to recurrence while treating early enough in the disease process to be meaningful (Ost et al, 2011a). Furthermore, in a propensity-matched analysis of adjuvant radiation therapy versus early salvage radiation (radiation delivered at a postoperative PSA ≤ 0.5 ng/mL) at least 6 months after radical prostatectomy, 2-year and 5-year biochemical free-survival were 91.4% and 78.4% for adjuvant therapy compared to

92.8% and 81.8% for early salvage radiation therapy, respectively (Briganti et al, 2012).

Clearly, randomized phase III clinical trials are desperately needed to determine the role of adjuvant radiation versus early salvage radiation therapy. As mentioned previously, the RADICALS trial is a multi-institutional phase III clinical trial examining adjuvant radiation within 22 weeks of surgery versus early salvage therapy at PSA relapse which is defined as either two consecutive rises in PSA level and a PSA value greater than 0.1 ng/mL or three consecutive rises in PSA (Parker et al, 2007). If biochemical recurrence is detected, patients will undergo either 66 Gy in 33 daily fractions over 6.5 weeks or 52.5 Gy on a 4-week treatment schedule. The Radiotherapy-Adjuvant Versus Early Salvage (RAVES) trial is a phase III trial randomizing patients with pathologic T3 disease and/or positive margins. Primary end point is biochemical cancer control with secondary outcomes including quality of life, toxicity, anxiety/depression, biochemical failure-free survival, overall survival, disease-specific survival, time to distant failure, time to local failure, time to initiation of androgen ablation, quality adjusted life years, and cost-utility. Finally, the French Groupe d'Étude des Tumeurs Uro-Génitales (GETUG-17) trial will evaluate a similar patient population but will randomize patients to immediate adjuvant radiation therapy versus observation patients and treating with salvage radiation when PSA levels reach a level of 0.2 ng/mL. Both groups will undergo a short course of ADT. As these trials complete accrual and mature, we will gain a better understanding about the timing of radiation therapy along with the utility of concomitant ADT.

Androgen Deprivation Therapy for Biochemical Failure after Radical Prostatectomy

ADT in the postprostatectomy setting has been underevaluated, and the scope of its utility is lacking. Unfortunately, randomized controlled trials are limited and the exact role in the comprehensive care of aggressive prostate cancer is not completely understood. Large retrospective series have demonstrated mixed results. Early ADT in men who have experienced biochemical recurrence has been found to decrease the rates of clinical metastasis in patients with high-risk features defined as Gleason sum greater than 7 or PSA doubling time less than 12 months (Moul et al, 2004). Delineation between early and late administration of androgen deprivation was significant at PSA cut points of 5 and 10 ng/mL (Moul et al, 2004). Similarly, the adjuvant ADT before signs of biochemical progression in select patients demonstrates improved 10-year progression-free and cancer-specific survival (Siddiqui et al, 2008). This was true even compared to a cohort of patients who received systemic therapy at PSA values of 0.4 ng/mL and above. Regardless of improvements in biochemical and cancer-specific outcomes, there is no evidence of improved overall survival (Siddiqui et al, 2008). Furthermore, the benefits in administration of ADT must be tempered by the potential for increased risk for cardiac disease and diabetes (Keating et al, 2006).

Not all patients who experience biochemical recurrence require ADT, and the identification of subgroups at highest risk for systemic failure will optimize selection and prevent morbidity. Patients with pathologic T3b tumors benefit from the adjuvant administration of ADT and experience improved 10-year biochemical progression-free survival of 60% versus 16% (Siddiqui et al, 2011). These patients also demonstrated improved local recurrence-free, systemic progression-free, and CSS. But again, there was no statistically significant improvement in overall survival (Siddiqui et al, 2011). Patients with high-risk features such as Gleason score of 8 or higher; PSA level 15 ng/mL or higher; pathologic stage T3b, T4, or N1; or Gleason score 7 with concomitant PSA value greater than 10 ng/mL or a positive margin, were found to have a biochemical failure-free survival of 92.5% at 5 years, with an overall survival of 95.9% in patients treated with adjuvant ADT as part of a randomized clinical trial (Dorff et al, 2011). Patients who have positive lymph nodes at radical prostatectomy are at highest risk for micrometastatic disease

and eventual systemic failure. In a randomized clinical trial of immediate versus deferred ADT, patients who received immediate therapy demonstrated improved overall survival, cancer-specific survival and progression-free survival at a follow-up of 11.9 years (Messing et al, 2006). Clearly, patients at the highest risk for local and systemic recurrence are those who likely benefit the most from adjuvant hormone therapy.

RADIATION THERAPY

Prostate-Specific Antigen Recurrence after Definitive Radiotherapy

Similar to PSA recurrence after radical prostatectomy, biochemical recurrence after definitive radiotherapy precedes clinical failure. This gives ample warning of potential disease progression to initiate secondary/salvage therapies. However, the definition of biochemical failure and threshold values has been controversial. In 1996, a multidisciplinary panel of experts met in San Antonio, Texas, to impart a definition of biochemical failure using the PSA. Their stated goals included creating a definition to be used in clinical practice as well as clinical trials. Furthermore, the definition should be valid for studies of dose intensity, brachytherapy, adjunctive hormones, and other systemic agents (American Society for Therapeutic Radiology and Oncology [ASTRO] Consensus Panel, 1997). The standard definition of PSA failure was determined as three consecutive rises in PSA level after a nadir PSA, with the date of failure as the midpoint between the nadir PSA and first failure. However, the panel made it a point to state that PSA failure is not equivalent to clinical failure and should not be used as a justification for additional treatment. Furthermore, PSA determinations should be obtained at 3- to 4-month intervals for at least 2 years and a minimum follow-up of 24 months completed before publication of any series (ASTRO Consensus Panel, 1997).

Although the ASTRO definition of biochemical failure with three consecutive rises above a nadir PSA created consensus among different series of definitive radiation, there were significant issues with the definition. Clearly, backdating biochemical failure biased event-free survival outcomes and was dependent on length of follow-up (Vicini et al, 1999; Thames et al, 2003). Furthermore, this definition was not linked to any clinically significant outcomes such as clinical failure or cancer-specific or overall survival. It also became evident that publications failed to incorporate patients with adequate follow-up (24 months), used the definition for alternative radiation methods, and included patients treated with ADT. In 2005, another multidisciplinary panel of experts met in Phoenix, Arizona, to discuss a new definition of biochemical failure after definitive radiation therapy for prostate cancer (Roach et al, 2006). This group defined PSA recurrence as a rise of 2 ng/mL or more above the nadir PSA and the date of failure was at call. Importantly, the stated biochemical outcomes should be 2 years short of the median follow-up for the group to avoid any overestimations of biochemical-free survival. Furthermore, the definition was created for use in patients who also received concurrent ADT (Roach et al, 2006).

It is now clear that the Phoenix definition of biochemical recurrence is more robust in predicting clinical outcomes. In a contemporary series of definitive radiotherapy for prostate cancer, 1831 men with clinical stage T1 to T4 prostate cancer without nodal or metastatic disease was compared using the ASTRO and Phoenix definitions of biochemical recurrence to predict for metastatic disease and cancer-specific and overall mortality (Abramowitz et al, 2008). Accounting for covariates such as T stage, initial hormonal treatment, Gleason score, radiation dosage, PSA level, and age, the Phoenix definition was found to be a significant predictor of metastatic disease, cancer-specific mortality, and overall mortality on univariate and multivariable analysis. The ASTRO definition was significant for metastatic disease and cancer-specific mortality to a lesser degree and not significant at all for overall survival (Abramowitz et al, 2008). In fact, on multivariable analysis,

PSA nadir + 2 ng/mL was the most significant predictor of all three outcomes compared to all other covariates confirming the validity of this definition of PSA recurrence (Abramowitz et al, 2008).

Postradiation Prostate-Specific Antigen Bounce

Postradiation PSA "bounce" is a varied definition of an elevated PSA of 0.1 to 0.5 ng/mL over the prebounce PSA level, with a subsequent decrease in PSA level (Cavanagh et al, 2000; Critz et al, 2000; Hanlon et al, 2001; Rosser et al, 2002). It is thought that this phenomenon occurs secondary to post-treatment prostatitis (Critz et al, 2000) or even from the delivery of a sublethal dosage of radiation with associated delayed cellular death. Rosser and colleagues (2002) defined PSA bounce among their cohort as a rise of PSA level of at least 0.5 ng/mL followed by a decrease to baseline value and found in their group of men that the bounce occurred at a mean time of 9 months from therapy and was associated with an improvement in biochemical recurrence-free survival compared to those who did not have a bounce. Conversely, Hanlon and colleagues (2001) defined PSA bounce as a rise in PSA level of at least 0.4 ng/mL over a 6-month period followed by a decrease in PSA level by any value. One third of their study cohort experienced a PSA bounce at a median time to bounce of 35 months (Hanlon et al, 2001). Although patients with a PSA bounce had 5-year biochemical rates of no evidence of disease (NED) of 52% versus 69% for those who did not bounce, the authors emphasize that clinicians should not use the existence of a PSA bounce as an indication of relapse. Series of brachytherapy in addition to external-beam radiation demonstrate similar rates of PSA bounce of approximately 35% (Cavanagh et al, 2000; Critz et al, 2000). It is quite clear that patients who undergo a transient rise in their PSA should be closely monitored, because not all men are destined for biochemical failure, let alone clinical failure.

Natural History of Prostate-Specific Antigen Recurrence after Definitive Radiation

PSA-only recurrence after definitive radiation therapy for prostate cancer leads to clinically relevant outcomes such as local and distant failure along with cancer-specific death. Lee and colleagues (1997) demonstrated in their cohort of 151 men that men with higher pretreatment PSA levels, higher Gleason scores, and higher stage were more likely to develop an increasing PSA profile (PSA \geq 1.5 ng/mL on two occasions). Furthermore, 5 years after PSA elevation, the estimated rate of local recurrence was 26% and distant metastasis was 47%. Overall survival and cause-specific survival (CSS) at 5 years were 65% and 76%, respectively. Although rapid PSA doubling time and short interval from treatment to PSA elevation were predictors of subsequent metastatic disease, Gleason grade was the only predictor for overall survival and CSS (Lee et al, 1997). Men with PSA elevation after definitive radiotherapy are candidates for salvage therapy. Defining those at greatest risk for local versus distant failure is key to deciding on second-line therapy. Further, patient comorbidity and age must be considered before the initiation of treatment.

Biopsy after Radiotherapy

The goals of biopsy after definitive radiation are to identify the presence or absence of locally residual or recurrent disease and to identify the grade of remaining disease. Crook and colleagues (2000) recommended biopsies to be performed at least 2 to 3 years after the completion of radiation therapy to decrease the rates of false-positive and false-negative biopsies. Biopsy based on ultrasound or magnetic resonance (MR) guidance should target abnormal lesions, the seminal vesicles, and a systematic sampling of the entire prostate gland. The information from prostate biopsy will guide further treatment strategies and should be reserved for patients in whom salvage local therapy is considered. One should keep in mind that tumor architecture is altered after radiation therapy

and may represent dedifferentiation of cancer cells. Further, Gleason grading after radiation therapy may or may not be accurate and its utility is controversial (Cheng et al, 1998, 1999; Letran and Brawer, 1998).

Imaging after Biochemical Recurrence Following Radiotherapy

Imaging of the prostate after definitive radiotherapy remains challenging with traditional modalities because of fibrosis and shrinkage of the prostate (Martino et al, 2011). TRUS has limited ability to identify suspicious lesions of the prostate and has a sensitivity and specificity profile no better than that of rectal examination (Crook et al, 1993). Furthermore, although CT is useful in patients with significantly elevated PSA levels (>20 ng/mL) for the detection of bone and lymph node metastasis, the ability to identify recurrent cancer after radiotherapy is limited. Recently, MRI has emerged as the most promising technique for identifying recurrent tumors of the prostate in biochemical recurrence.

T2-weighted MRI of the prostate is capable of excellent soft tissue differentiation; however, its use in postirradiated tissue is limited by diffusely decreased signal intensity in the prostate (Coakley et al, 2001). Sensitivity of T2-weighted MRI is as low as 27%, with limited positive predictive value of 32% (Kim et al, 2010). Therefore dynamic imaging studies have been pursued to better identify potential recurrent lesions amenable for salvage therapy. DCE gives the ability to identify vascularization of the prostate and tumor along with angiogenesis and capillary permeability characteristics (Franiel et al, 2011). When comparing DCE-MRI with T2-weighted MRI, DCE-MRI had better sensitivity (72% vs. 38%), positive predictive value (46% vs. 24%), and negative predictive value (95% vs. 88%). Specificity was similarly high for both groups (Haider et al, 2008). Yakar and colleagues (2010) determined that the combination of DCE imaging along with MR-guided biopsy of suspicious lesions led to a positive predictive value of 75% and 68% per patient and per tumor suspicious region, respectively.

MR spectroscopy distinguishes residual prostate cancer by identifying a relative increase of choline plus creatine-to-citrate ratio or by identifying an increase in the choline peak with no citrate identified. Using these criteria, MR spectroscopy has demonstrated sensitivity of 77% compared to sextant biopsy and rectal examination, which revealed sensitivities of 48% and 16%, respectively, in the same patient cohort (Pucar et al, 2005). However, it is important to note that benign glands can exhibit high choline levels after radiation and may cause false positive findings (Pucar et al, 2005). Furthermore, the addition of MR spectroscopy to T2-weighted imaging significantly improved the detection of locally recurrent prostate cancer after radiation therapy (Westphalen et al, 2010).

Diffusion-weighted imaging MRI (DWI-MRI) also has demonstrated feasibility in the clinical setting. Kim and colleagues found the utility alone and in combination with DCE imaging revealing an accuracy of biopsy as high as 83% (Kim et al, 2010). This was in comparison to T2-weighted MR, which demonstrated an accuracy rate of 67%. Further illustrating the benefit of DWI-MRI, Hara and colleagues (2012) found a sensitivity and specificity of 100% and 100%, respectively, on a per-patient basis when comparing MRI findings to a 22-core 3D prostate-mapping biopsy as the standard reference. On a region-by-region basis, the sensitivity and specificity were 69% and 91%, respectively. These data demonstrate the utility of MRI in patients with biochemical recurrence after radiation therapy. The optimal timing of MRI and level of PSA at imaging are yet to be determined and will need further investigation.

Salvage Radical Prostatectomy

Salvage radical prostatectomy is considered the most definitive way to eradicate localized radiorecurrent prostate cancer. Despite the infrequent use of salvage surgery in the setting of radiorecurrence, multiple studies have demonstrated the 10-year cancer-specific survival to be as high as 70% to 83% (Lerner et al, 1995; Bianco et al,

2005; Ward et al, 2005; Chade et al, 2011). However, survival outcomes directly correlate with pathologic stage whereby organ-confined disease and isolated extracapsular extension confer a 5-year progression-free probability of 77% and 71%, respectively. Conversely, those with seminal vesicle invasion and lymph node involvement have poorer 5-year outcomes of 28% and 22%, respectively (Bianco et al, 2005; Stephenson and Eastham, 2005). Given the high propensity for prostate cancer to recur despite radiation therapy, it is of utmost importance to treat with definitive salvage therapy before local invasion and metastasis. Preoperative PSA functions as a predictor of disease, because approximately two thirds of patients with a PSA lower than 10 ng/mL will have organ-confined disease. Furthermore, these patients have a 5-year progression-free probability of approximately 70% (Stephenson and Eastham, 2005). In a modern series of salvage prostatectomy after contemporary radiation, Heidenreich and associates (2010) found that 73% of patients had organ-confined disease, of which PSA doubling time of greater than 12 months, previous brachytherapy, and less than 50% of the biopsy core positivity were predictors of organ confinement, margin negativity, and lymph node negativity.

Despite successful cancer outcomes in traditional and contemporary series of salvage radical prostatectomy, the hesitance to perform such operations is due to the inherent risks for significant morbidity. Historically, up to 50% of patients who undergo salvage surgery will experience a major complication (Moul and Paulson, 1991). As a result of significant fibrosis from radiation, rectal injury rates of 6% to 15% and bladder neck contracture rates of 20% to 28% have been reported. Further, rates of urinary incontinence ranged from 40% to 60% (Lerner et al, 1995; Rogers et al, 1995). It is worth mentioning that in these surgical series, some patients had received preradiation pelvic lymph node dissection, retropubic brachytherapy, and nonconformal radiation delivery, which added to the morbidity. Because of the high complication rates, clinicians have been hesitant to perform salvage radical prostatectomy. This is reflected in the Cancer of the Prostate Strategic Urology Research Endeavor (CaPSURE) database, demonstrating that only 2% of patients underwent surgery as secondary treatment after radiation failure whereas 92% underwent noncurative ADT (Grossfeld et al, 2002).

With improved surgical techniques and patient selection, the morbidity in modern series of salvage radical prostatectomy has improved dramatically. In fact, major complication rates were reduced from 33% to 13% in one series, with rectal injury rates of 2% to 4% (Stephenson et al, 2004a; Heidenreich et al, 2010). Clearly, better surgical planning, meticulous attention to anatomy, and improved radiation delivery have played a major role in improved morbidity. Continence rates are now seen in the 70% to 80% range, and modern series even demonstrate that 16% to 18% of men can achieve erections sufficient for intercourse with or without the aid of PDE5 inhibitors (Stephenson et al, 2004a; Heidenreich et al, 2010). Given the improvement in morbidity outcomes and the knowledge that long-term cancer-specific outcomes can be achieved with radical surgery, patients who are at risk for radiation failure should be identified early and encouraged to undergo definitive therapy. However, because of the risk for devastating complications such as fistula, patient selection is of the utmost importance. **Patients selected for salvage radical prostatectomy should have biopsy-proved radiorecurrent prostate cancer, at least 10 years of life expectancy, lack of identifiable metastasis on imaging, and a PSA level of less than 10 ng/mL (Table 119-2).**

Within the last 10 years, there has been a preponderance of robotic-assisted laparoscopic prostatectomy procedures and, naturally, this approach has begun to gain favor among urologists willing to tackle salvage prostatectomy. Perceived advantages to the robotic approach include decreased blood loss, better visualization, and shorter hospitalization. There have been several smaller series of patients reporting both oncologic and morbidity outcomes in patients undergoing robotic salvage prostatectomy. In the two largest series, the biochemical failure rates were reported to be 18% and 33%. However, median follow-up in these series was limited

TABLE 119-2 Outcomes of Salvage Radical Prostatectomy for Radiorecurrent Prostate Cancer

STUDY	N	YEARS	MEDIAN FOLLOW-UP (yr)	% DISEASE-FREE INTERVAL (yr)	% CANCER-SPECIFIC SURVIVAL (yr)
Chade et al, 2011	404	1985-2009	4.4	37.5 (10)	83 (10)
Paparel et al, 2009	146	1984-2006	3.8	54 (5)	—
Ward et al, 2005	138	1967-2000	6.4	—	90 and 77 (5, 10)
Bianco et al, 2005	100	1984-2003	5	55 and 30 (5, 10)	73 and 60 (10, 15)

at 16 and 18 months, respectively (Eandi et al, 2010; Kaffenberger et al, 2013). Long-term studies are necessary to demonstrate oncologic efficacy. One area in which robotic surgery has shown equivalence if not improvement is in morbidity. In the three largest series of robotic salvage prostatectomy, only 1 of 63 patients has been reported to have suffered a rectal injury, six patients had bladder neck contractures, and 12 patients had anastomotic leakage. Urinary continence rates have been reported to range from 33% to 80%, depending on definition and follow-up (Boris et al, 2009; Eandi et al, 2010; Kaffenberger et al, 2013). Because both data and surgeon experience mature, both oncologic and morbidity outcomes will likely demonstrate improvement. Similar to open surgery, patient selection and close adherence to surgical principles are of utmost importance.

Salvage Cryotherapy

In the United States, approximately one third of men newly diagnosed with prostate cancer are treated with external-beam radiation and/or brachytherapy as the primary modality of therapy (Mettlin et al, 1998, 1999). Depending on the series and definition, approximately 30% to 40% of patients treated with primary radiation will have failure (Shipley et al, 1999; Crook et al, 2000; Touma et al, 2005; D'Amico et al, 2008). In the carefully selected patient, cryotherapy may be an effective and safe option for treatment of radio-recurrent disease.

Patients best suited for cryotherapy are those with localized treatment failure after radiation therapy with biopsy-proved disease, because approximately one third of patients with biochemical failure will have a positive biopsy result (Crook et al, 1995). Regardless of definition, biochemical failure determination and histologic failure are ideally identified at least 2 years after primary treatment to account for PSA bounce and ongoing histologic changes after radiation (Crook et al, 2000; Chin et al, 2007). In addition to standard multicore prostate biopsy, it may be prudent to include the seminal vesicles, because up to 29% may have involvement and predict for poor outcomes (Gheiler et al, 1998). Candidates for salvage cryotherapy should have a reasonable life expectancy and must undergo a full metastatic workup with cross-sectional imaging (CT abdomen/pelvis or MRI), along with a radionuclide bone scan (Babaian et al, 2008). Pelvic lymph node biopsy also may be considered in high-risk patients (Babaian et al, 2008). A presalvage PSA level of less than 10 ng/mL (ideally < 4 ng/mL) (Ng et al, 2007) and a PSA doubling time of 16 months or longer have been shown to be predictive for successful treatment (Spiess et al, 2006).

To date, there is no universal definition of success using salvage cryotherapy. Using a definition of 2 ng/mL above the postcryotherapy nadir, Pisters and colleagues demonstrated a 74% 2-year disease-free survival for patients with postradiation PSA less than 10 ng/mL and 58% for patients with preradiation Gleason score of 8 or less (Pisters et al, 1999). In a contemporary analysis of the COLD (cryo online data) Registry including 156 patients, 3-year biochemical disease-free survival using the Phoenix definition of nadir + 2 ng/mL was determined to be 66.7% (Spiess et al, 2013). Williams and associates (2011) report their outcomes in 176 patients with a mean follow-up of 7.46 years. Primary outcome of overall survival was 95%, 91%, and 87% at 5, 8, and 10 years,

respectively. Biochemical disease-free survival using the Phoenix definition was determined to be 47%, 39%, and 39%, respectively. Patients with a postcryotherapy nadir of greater than 1 ng/dL had a 6.6 times higher risk for recurrence, and 5-year disease-free survival was only 3%, highlighting this as an important prognostic factor.

Clearly, the success of any salvage therapy is tempered by the significant risks for side effects. Third-generation cryotherapy involves the adoption of a liquid argon gas system, smaller diameter probes, pinpoint thermocoupler, and continued use of TRUS guidance and urethral warmers. Historically, salvage cryotherapy was wrought with a high complication rate. In terms of urinary morbidity, one of the largest quality-of-life series of 112 men demonstrated 72% of men had urinary incontinence, with 66% of men describing their symptoms as moderate to severe. Only 33% felt satisfied by the therapy they had received (Perrotte et al, 1999). However, more recent data demonstrate improved urinary incontinence rates from 4.3% to 6.5% (Bahn et al, 2003; Donnelly et al, 2005; Pisters et al, 2008). This drastic improvement in results is likely due to the universal use of urethral warming, which helps protect the urinary sphincter mechanism. Erectile dysfunction has been difficult to gauge in salvage cryotherapy series secondary to inconsistent reporting and lack of validation. In the series from Perrotte and colleagues (1999), 15% of patients who were potent before treatment maintained erectile function sufficient for sexual intercourse. Ismail and coworkers (2007) report a rate of erectile dysfunction of 86%. Clearly, erectile dysfunction is a significant risk from the primary treatment and further cryotherapy is likely to worsen symptoms. Current exploration into nerve sparing and subtotal cryotherapy is underway. The most dreaded complication risk for salvage cryotherapy is urethrorectal fistula, which has decreased significantly in recent series. Current reports demonstrate more acceptable rates of 1% to 3.4% (Bahn et al, 2003; Ismail et al, 2007; Ng et al, 2007; Pisters et al, 2008). Other reported complications include urinary obstruction, urethral sloughing, urethral stricture, rectal pain, scrotal edema, and hematuria (Chin et al, 2007; Finley and Beldegrun, 2011). It is clear that in the carefully selected patient, salvage cryotherapy is a reasonable approach with adequate cancer-specific outcomes and limited morbidity (Table 119-3).

Salvage Brachytherapy

The evidence for salvage brachytherapy after radiation failure is lacking compared to salvage prostatectomy and salvage cryotherapy. However, several groups have published contemporary series, including modern techniques that not only demonstrate improved cancer control outcomes but also have comparable morbidity outcomes to those with cryotherapy and surgery. Randomized controlled trials of salvage therapies are desperately needed.

Burri and colleagues published their series of salvage brachytherapy after local failure with long-term follow-up (median 86 months). Before therapy, patients underwent a thorough evaluation with history and physical examination, routine laboratory studies, pelvic CT, bone scan, and PSA level. Furthermore, all patients had biopsy-proved local failure, including 30 men who underwent six-core seminal vesicle biopsy. At 10 years, patients had a 54% freedom from biochemical failure, 96% cancer-specific survival, and 74% overall survival (Burri et al, 2010). Interestingly, 11 patients

ASTRO, American Society for Therapeutic Radiology and Oncology; LUTS, lower urinary tract symptoms; PSA, prostate-specific antigen (test).

underwent prostate needle biopsy at a median of 38 months; 6 of these had planned biopsy without signs of biochemical or local failure. Of these 6 patients, 4 had evidence of local failure. Toxicity was comparable to that of other salvage modalities, with 13 patients having grade 2 toxicity (obstructive urinary symptoms, urge incontinence, diarrhea), 3 patients with grade 3 toxicity (obstructive uropathy requiring TURP, fulguration for gross hematuria), and 1 patient with a grade 4 toxicity (urinary diversion for a prostatic fistula) (Burri et al, 2010). Furthermore, 25% of men who had pretreatment erectile function had at least sufficient erectile function for intercourse. A similar series of salvage brachytherapy demonstrates a cancer-free survival of 96% and biochemical relapse-free survival of 88% at a median follow-up of 30 months (Aaronson et al, 2009). This group also reports 1 patient with grade 2 urethral stricture, 5 patients with grade 2 gross hematuria, and 1 patient with grade 3 rectal hemorrhage. No patients had evidence of fistula (Aaronson et al, 2009). The evidence for salvage brachytherapy demonstrates a potential role after radiation failure. As with other treatment modalities, there is significant risk for morbidity. Therefore a thorough risk assessment of patients' other comorbidities must be evaluated, because some patients will succumb to other comorbidities. In fact, in 10 men who died during follow-up after salvage brachytherapy, only one was attributable to prostate cancer (Burri et al, 2010).

High-dose rate brachytherapy (HDRB) has gained attention because it has the ability to implant the seminal vesicles and treat extracapsular extension while limiting the dosage to surrounding organs through a conformal delivery (Syed et al, 2001; Hsu et al, 2005; Chen et al, 2013). In the largest series of HDRB, 52 patients underwent therapy with a median follow-up of 59.6 months. All patients had biopsy-confirmed recurrent disease, negative workup for systemic disease, and no previous prostatectomy. Patients received 36 Gy in six fractions in two separate implants a week apart (Chen et al, 2013). Five-year overall survival was 92% and biochemical recurrence-free survival was 51%. As expected, patients with lower post-therapy nadir were more likely to have biochemical-free survival (Chen et al, 2013). Only one patient had distant failure, with a nadir PSA of 7.2 ng/mL. Toxicity profile was excellent in this cohort, with only 1 patient having a grade 3 acute and late GU toxicity and no patients having any grade 3 or 4 acute or late GI toxicity (Chen et al, 2013). Whereas no factors were statistically significant as predictors for biochemical outcome, the factors that were borderline in significance were disease-free interval after initial definitive radiation, percent of positive cores at diagnosis, time from recurrence to salvage HDRB, and presalvage therapy PSA (Chen et al, 2013). Salvage HDRB is a promising modality for patients with radiorecurrent prostate cancer. As with low-dose rate brachytherapy, patients likely to be most suitable are those with prolonged disease-free interval from primary treatment to recurrence, longer PSA doubling times, Gleason score 6 or less, PSA level less than 10 ng/mL, and no evidence of extracapsular extension or seminal vesicle invasion (Beyer, 2003).

Salvage High-Intensity Focused Ultrasound

Salvage high-intensity focused ultrasound (HIFU) has been evaluated in the treatment of radiorecurrent prostate cancer with acceptable cancer control outcomes. In a large series of 167 men treated with HIFU for recurrent prostate cancer, local cancer control as defined by a negative prostate biopsy result was achieved in 122 (73%) of patients (Murat et al, 2009). Three-year progression-free survival was 53%, 42%, and 25% for the low-, intermediate-, and high-risk groups, respectively. Treatment with HIFU was associated with urinary morbidity, including urinary retention, urinary tract infection, urinary incontinence, and bladder outlet obstruction. Five patients developed a urethrorectal fistula. Similarly, in 46 patients undergoing salvage HIFU, 18 patients (39%) were deemed failures after a median follow-up of 9 months. One patient had a urethrorectal fistula, and two patients experienced urethrocuteaneous fistula (Berge et al, 2010). Although short- to intermediate-term follow-up has been demonstrated with HIFU, further studies are

necessary to establish its place as a viable alternative in the radio-recurrent setting.

Androgen Deprivation Therapy after Biochemical Recurrence Following Radiation Therapy to the Prostate

PSA elevation after definitive radiotherapy may be due to local versus distant metastatic disease. Patients with biopsy-proved local disease, no evidence of distant metastatic disease, and substantial life expectancy should be counseled about salvage local therapy such as prostatectomy, radiation approaches, and cryotherapy. Some patients may refuse local therapy, may have too many comorbidities to undergo potentially morbid procedures, or have decreased life expectancy. Even in younger patients who are candidates for local therapy, survey results demonstrate that up to 54% of clinicians would recommend observation or ADT. This is more pronounced in a scenario of older men, 78% of whom would be recommended for observation or ADT (Sylvester et al, 2001). The reality is that 93.5% of men undergo ADT as second-line therapy after radiation failure, and therefore this approach should be clearly defined (Agarwal et al, 2008).

Not all patients with biochemical recurrence after radiation approaches are destined for clinical failure. Defining the patient population who are at highest risk is important to treat the patients with early ADT who are likely to benefit while sparing the significant side effects to those who are at low risk to fail. PSA doubling time has consistently demonstrated the ability to predict for patients who are at highest risk for failure after radiotherapy and has been linked to freedom from biochemical recurrence, local relapse, distant metastasis, and overall survival (Pollack et al, 1994; Hanks et al, 1996; Lee et al, 2005; Zelefsky et al, 2005). Although multiple cut points under 12 months have been described to be significant for increased risk for clinical failure, it is likely that this end point is linear (D'Amico and Hanks, 1993); thus clinical judgment must be used, taking into consideration the patient's comorbidities and likelihood of prostate cancer-related death for the initiation of ADT. Furthermore, side effects of ADT therapy, including sexual side effects, hot flashes, decreased bone mineral density, decreased muscle mass, cognitive dysfunction, metabolic syndrome, potential cardiovascular morbidity, fatigue, anemia, and depression, must be taken into consideration (Green et al, 2002; Cherrier et al, 2003; Higano et al, 2004; Harle et al, 2006; Keating et al, 2006; D'Amico et al, 2007; Spry et al, 2009).

Considering the potential morbidity of ADT and the substantial cost, it is reasonable to start treatment in those patients at highest risk for distant failure. This is confirmed as patients with PSA doubling times less than 12 months have been demonstrated to benefit from ADT, with freedom from distant metastatic disease of 57% versus 78%. Further, patients who received ADT had median time from distant failure of 6 months compared to 25 months (Pinover et al, 2003). This benefit of therapy with ADT was not seen in the patient cohort with PSA doubling time greater than 12 months, confirming the notion that patients at decreased risk for systemic disease are unlikely to benefit from the early initiation of systemic therapy. Faria and colleagues (2006) reviewed their series of 113 men with long PSA doubling time of 26.4 months who experienced biochemical failure but did not undergo ADT. At a median follow-up of 43 months, no patients had died of prostate cancer but 12 patients had died from other causes (Faria et al, 2006). These data illustrate the importance of risk stratification in patients after biochemical recurrence following radiation therapy. The exact timing of ADT after failure is unknown, and results of clinical trials such as NCT00110162 examining the role of immediate versus delayed ADT in PSA-only recurrence are desperately needed (<http://ClinicalTrials.gov>, 2009). Finally, the ideal management of PSA recurrence in patients at high risk for failure may be the initiation of intermittent ADT. In a recent clinical trial, intermittent ADT was found to be noninferior compared to continuous therapy in patients with PSA levels greater than 3 ng/mL without evidence of metastatic disease. This came with the benefit of potential improvement in

physical function, fatigue, urinary problems, hot flashes, libido, and erectile function (Crook et al, 2012). Further studies are necessary to identify the ideal timing of ADT initiation, the benefits of intermittent ADT, and the ideal patient group who will benefit the most from therapy.

CRYOTHERAPY

Management of Biochemical Recurrence after Definitive Cryotherapy in Prostate Cancer

The determination of biochemical failure after definitive cryotherapy of the prostate for cancer is extremely varied in the literature. In fact, neither the AUA Best Practice Statements for PSA testing nor those for cryotherapy define what is considered a biochemical recurrence after whole-gland cryotherapy of the prostate (Babaian et al, 2008; Carroll et al, 2012). Biochemical recurrence after cryotherapy has been defined as PSA levels greater than 0.5 ng/mL, greater than 1.0 ng/mL, the ASTRO definition (three consecutive rises in PSA), and the Phoenix definition of nadir + 2 ng/mL (Shinohara et al, 1997; Koppie et al, 1999; Long et al, 2001; Bahn et al, 2002; Babaian et al, 2008; Cohen et al, 2008). A unifying definition that consistently predicts for clinical failure (local failure, metastatic disease, cancer-specific and overall survival) is needed. Further investigation is warranted to determine these values and definitions.

Depending on the definition used for biochemical recurrence, success rates of cryotherapy are extremely varied. Long and colleagues (2001) examined a group of 975 men who underwent cryotherapy as primary therapy for prostate cancer. Overall 5-year biochemical recurrence-free survival was 52% using a cutoff of 0.5 ng/mL and 63% using a cutoff of 1.0 ng/mL. Another group using a definition of biochemical failure as PSA nadir 0.5 ng/mL or greater or subsequent biochemical failure defined as PSA level increase of 0.2 ng/mL or greater for their cohort of 134 men (Shinohara et al, 1997). They determined that PSA nadir is an important factor in determining the risk for subsequent biochemical recurrence such that patients who achieved a nadir less than 0.1 ng/mL had a 21% risk for failure compared to 46% in patients who had a nadir above 0.5 ng/mL. Furthermore, patients with a nadir below 0.1 ng/mL had a biopsy failure rate of 7% compared to 60% in those who had nadir values of 0.5 ng/mL or greater. Further, in a large cohort of 590 patients with 5.4 years of follow-up, a PSA-based definition of biochemical failure of 0.5 ng/mL was compared to a definition of 1.0 ng/mL and to the ASTRO definition of three successive increases in PSA level. In patients with low-, medium-, and high-risk prostate cancer before therapy, the 7-year actuarial freedom from biochemical failure was 61%, 68%, and 61% for a cutoff of 0.5 ng/mL; 87%, 79%, and 71% for a cutoff of 1.0 ng/mL; and 92%, 89%, and 89% when using the ASTRO definition (Bahn et al, 2002). In a series with robust follow-up, Cohen and colleagues (2008) demonstrated 10-year biochemical disease-free survival of 80.1%, 74.2%, and 45.6% for low-, moderate-, and high-risk groups, respectively, using the Phoenix definition of biochemical failure. These data illustrate the importance of a unifying definition for PSA failure. Local failure tended to occur at the apex and seminal vesicles in this cohort. These data clearly indicate the vigilance necessary in patients after treatment with cryotherapy. Patients who have higher PSA nadir and post-treatment positive biopsies should be counseled about secondary treatment strategies to decrease risk for potential subsequent disseminated disease. Management strategies for cryotherapy failure are lacking, and the literature is incomplete for treatment options.

The case for repeated cryotherapy administration is based on small patient numbers. Koppie and colleagues (1999) reported their results with cryotherapy and found that in patients who underwent repeated cryotherapy for initial failure, only 8 of 24 patients achieved biochemical freedom from recurrence, defined as a PSA nadir of less than 0.5 ng/mL and without an increase of PSA level by more than 0.2 ng/mL on two consecutive occasions. Conversely, Bahn and others (Bahn et al, 2002) demonstrated a relatively favorable outcome in 31 patients undergoing repeated treatment with

5-year freedom from biochemical failure of 68%, 72%, and 91% based on definitions of 0.5 ng/mL, 1.0 ng/mL, and the ASTRO criteria (Bahn et al, 2002). The relative success rates of repeat treatments must be somewhat tempered by the risk for significant morbidity, especially in light of previous therapy (Cox and Crawford, 1995).

Salvage radiation therapy after failure of cryotherapy has been described in multiple series. Patients who have failed cryotherapy as defined by PSA recurrence and/or positive biopsy should undergo a directed history, physical examination, and evaluation to rule out locally advanced or distant metastatic disease. Choi and colleagues (2013) describe their results in nine patients with recurrent prostate cancer after cryotherapy using IMRT. They describe dosages of 72 to 81 Gy with minimal side effects and no patients experiencing grade 3 or higher toxicities. With a mean pretreatment PSA of 4.3 ng/mL, biochemical control using the ASTRO definition of three subsequent rises of PSA level, was achieved in seven patients at a median follow-up of 20.5 months (Choi et al, 2013). Other series of patients undergoing salvage radiation therapy after failed cryotherapy demonstrate biochemical control rates of 61% to 75% at median follow-up of 32 to 34 months (Burton et al, 2000; McDonough et al, 2001; Hepel et al, 2008). These success rates are high despite the inclusion of patients with intermediate- and high-risk disease, making salvage radiation therapy a feasible choice after cryotherapy failure.

Evidence for salvage radical prostatectomy after cryotherapy failure is lacking. In an early series, Grampas and colleagues describe their method using radical perineal prostatectomy in six patients with biopsy-confirmed, stage T3 prostate cancer. Although the authors described increased fibrosis, excessive bleeding, and distorted anatomy, there were no intraoperative or postoperative complications and the time of operation and hospital stay were no different from those with the standard primary perineal prostatectomy (Grampas et al, 1995). Furthermore, five of six patients achieved PSA levels less than 0.2 ng/mL and morbidity outcomes revealed only temporary incontinence and impotence (Grampas et al, 1995). More recently, a case of cryotherapy failure treated with salvage robotic prostatectomy has been described in a man with pathologic T3b, Gleason 5+3 recurrent prostate cancer. With the addition of complete ADT, his follow-up PSA level at 10 months was undetectable (Rodriguez et al, 2007). Total operative time reported was 210 minutes, blood loss was 50 mL, and hospital stay was 24 hours. There is a deficit in the literature describing salvage prostatectomy after cryotherapy for prostate cancer. However, similar to salvage prostatectomy after radiation therapy, acceptable results are likely in the hands of surgeons with high operative volume. The best candidates for salvage surgery are those with adequate life expectancy (longer than 10 years) and absence of metastatic disease.

HIGH-INTENSITY FOCUSED ULTRASOUND

Management of Biochemical Recurrence after Definitive High-Intensity Focused Ultrasound in Prostate Cancer

HIFU is considered by most as a minimally invasive modality for the treatment of localized low to intermediate grade prostate cancer. Despite the increasing popularity and use of this treatment modality, HIFU is classified as experimental according to the European Association of Urology Guidelines and remains unregistered in the United States (Heidenreich et al, 2012). Historically, the lack of long-term data on clinical efficacy and morbidity has limited the wide-spread use of HIFU. Furthermore, a lack of definitive definition on treatment-related success or failure has limited the ability to compare this modality to other definitive treatment options for localized prostate cancer. Although most groups agree that a positive biopsy result after HIFU is a treatment failure, there are myriad definitions for biochemical failure, including three consecutive rises of PSA level and the Phoenix definition of biochemical failure (Gelet et al, 2001; Uchida et al, 2009). After a careful review of multiple definitions for biochemical failure, Blana and colleagues

(2009) determined that PSA nadir + 1.2 ng/mL, the Stuttgart definition, was the most effective at predicting for clinical failure and has been proposed as the definition for biochemical failure after HIFU for prostate cancer.

In general, success rates after primary HIFU for localized prostate cancer are comparable to those with other treatment modalities. In a study of 227 patients with clinical T1 to T2, PSA level of 15 ng/mL or less, Gleason score of 7 or less, and prostate volume 40 mL or lower, the actuarial 5-year disease-free survival rate combining pathologic and biochemical outcomes was 66% (Poissonnier et al, 2007). Biochemical recurrence was defined in this cohort as a PSA greater than 1 ng/mL with three consecutive rises over the nadir PSA. Significant success rates were seen stratified by pretreatment PSA with 90% in those with PSA level of 4 ng/mL or less, 57% for those with a PSA level of 4.1 to 10 ng/mL, and 61% for patients with PSA level of 10.1 to 15 ng/mL. In a similar series of 140 men, the Phoenix definition of biochemical failure was applied with an actuarial biochemical failure-free survival rate at 5 and 7 years of 77% and 69%, respectively (Blana et al, 2008). Prostate volume before therapy and PSA nadir (PSA 0.5 ng/mL) were statistically significant independent predictors of biochemical failure. Therefore, it is safe to assume that ideal candidates for HIFU are those with clinically localized prostate cancers (T1 to T2), low PSA (<15 ng/mL), and low prostate volumes. Furthermore, patients who exhibit earlier detection of biochemical recurrence (regardless of the definition) and higher nadir PSA values are at high risk for failure and should be evaluated for potential salvage strategies.

One such strategy in localized failure of HIFU is salvage radiotherapy. Although the literature is lacking on such approaches, Riviere and colleagues (2010) published their large series on conformal radiation to a median dose of 72 Gy after local recurrence after HIFU. One hundred patients with approximately 3 years of follow-up were included in this evaluation. For patients with radiation only (83 patients), the 5-year progression-free survival was 72%. Stratified by risk groups, the 5-year rates were 93%, 67%, and 55% for the low-, intermediate-, and high-risk groups, respectively. On multivariable analysis, the PSA nadir using a threshold of 0.2 ng/mL was predictive of eventual failure. Although GI toxicity was low in this cohort of men, there were four grade 3 (4.7%), one grade 4 (1.2%), and one grade 5 (1.2%) urinary toxicity. The single death was after a cystectomy for hemorrhage. Obviously, larger series with more robust patient numbers will be required to establish radiation approaches after HIFU as standard of care.

Another approach to the patient with localized failure after HIFU is salvage radical prostatectomy. Again, treatment numbers are lacking and small series of men provide us with the most information to date. To that effect, the largest series of patients undergoing surgery after HIFU includes 15 men. Presalvage radical prostatectomy Gleason scores were 6 (3), 7 (9), 8/9 (3), with a median core biopsy involved of 42% (Lawrentschuk et al, 2011). Furthermore, the pretreatment median PSA was 3.8 ng/mL. Pathology after salvage prostatectomy demonstrated a high rate of increased stage with 9 of 14 men having pT3 prostate cancer. Of 15 men, 4 had a positive apical margin. Most interestingly, all patients on evaluation had residual, viable prostate cancer in the HIFU-treated zones of the prostate (Lawrentschuk et al, 2011). Despite the unfavorable pathologic findings on salvage prostatectomy, 13 of 15 men were found to have unrecordable PSA (<0.05 ng/mL) postoperatively. Surgical management revealed significant extensive periprostatic fibrosis, but despite these findings, continence rates in those with 12 months of follow-up (10 patients) were reasonably good, with 6 (60%) requiring no pads, 3 (30%) patients using 1 safety pad, and only 1 patient remaining incontinent at 18 months of follow-up. As expected, erectile function in this cohort was universally poor. It is obvious that surgical management after local therapy with HIFU is a more difficult operation with higher risk for post-therapy morbidity. It is also clear that despite localized therapy and low levels of PSA even at recurrence (median PSA 3.8 ng/mL), patients uniformly had higher stage and all patients had viable prostate cancer in the treatment zones. Therefore patients who demonstrate any rise in PSA after HIFU should be watched vigilantly; after distant

metastatic disease workup, patients with significant life expectancy should be offered salvage local therapy earlier rather than later. Furthermore, patients interested in local HIFU therapy should be counseled before therapy about the risk for residual disease and the potential need for secondary therapy if failure occurs.

SUMMARY

Patients who experience biochemical recurrence after primary therapy of prostate cancer are at higher risk for clinical progression as well as anxiety from disease progression. However, not all men with PSA progression will experience clinically significant outcomes such as metastasis, need for secondary treatment, and death from prostate cancer. Therefore risk stratification is of the utmost importance. Furthermore, advances in diagnostic imaging and therapeutics will improve the identification of those with local recurrence and enhance cancer eradication with limited morbidity.

KEY POINTS

- The AUA guidelines panel defined PSA recurrence as a value of 0.2 ng/mL or greater with a second confirmatory laboratory value. However, the risk for clinical failure (metastatic disease, need for second-line treatment, and death from prostate cancer) depends on multiple variables.
- Prognostic models (nomograms) for PSA recurrence both before and after definitive therapy of the prostate should be incorporated into clinical practice for patient counseling.
- Traditional imaging modalities (bone scan and CT scan) are of limited value in early PSA recurrence; newer imaging techniques such as multiparametric MRI and PET scanning may demonstrate more utility at lower PSA values.
- Patients at high risk for clinical failure after radical prostatectomy (extracapsular extension, seminal vesicle invasion, and positive margins) should be offered adjuvant radiotherapy based on randomized controlled trials.
- Early salvage radiation may offer the benefit of treatment at low disease burden while sparing therapy for those never destined for local failure. Randomized controlled trials are underway to answer this treatment dilemma.
- Candidates of local therapy after radiation failure must have biopsy-proved local recurrence, adequate life expectancy (at least 10 years), absence of metastatic disease, and a PSA less than 10 ng/mL.
- Patients considered for second-line definitive therapy after radiation, HIFU, and cryotherapy should be counseled extensively on the risk for subsequent treatment-related morbidity.

[Historical Overview](#)[Molecular Biology of Androgen Axis](#)[Sources of Androgen](#)[Mechanisms of Androgen Axis Blockade](#)[Response to Androgen Blockade](#)[General Complications of Androgen Ablation](#)[Combination Therapy](#)[Timing of Therapy](#)[Economic Considerations](#)

HISTORICAL OVERVIEW

The response of prostate cancer to androgen ablation is among the most reproducible, durable, and profound of any systemic therapy for a solid tumor. The early and frequent descriptions of immediate relief of bone pain from metastatic prostate cancer following castration do not diminish the marvel of observing this phenomenon first hand. As is the case with many paradigm-shifting observations, endocrine therapy was based on a simple hypothesis. Described as a “biological syllogism,” [Huggins \(1947\)](#) noted a major premise, “In many instances a malignant prostatic tumor is an overgrowth of adult epithelial cells”; a minor premise, “All known types of adult prostatic epithelium undergo atrophy when androgen hormones are greatly reduced in amount”; and a conclusion, “Therefore, significant improvements should occur in the clinical condition of patients with far advanced prostate cancer subjected to castration.”

It had been known for at least a century that prostatic epithelium undergoes atrophy after castration ([Hunter, 1840](#)). The breakthrough in Huggins’s hypothesis was the recognition that benign prostatic epithelium and prostate carcinoma were biochemically analogous and they would respond in a similar fashion to androgen ablation. Emphasizing the importance of basic observations (“The evidence for the facts which represent the premises was obtained entirely in the laboratory” [[Huggins, 1944](#)]), studies on acid phosphatase provided the crucial link between benign and malignant prostate cells. Large amounts of acid phosphatase were found in the prostate glands of men and monkeys ([Kutscher and Wohlbergs, 1935](#)) as well as in primary and metastatic prostate cancer ([Gutman et al, 1936](#)), and the levels increased with androgen administration ([Gutman and Gutman, 1939](#)). Serum levels of acid phosphatase were increased in men with disseminated prostate cancer ([Barringer and Woodard, 1938](#); [Gutman and Gutman, 1938](#)). With localization of the enzyme to prostatic epithelial cells and primary and metastatic prostatic cancer cells ([Gomori, 1939](#)), the stage was set for Charles Huggins, R. E. Stevens, and Clarence V. Hodges to test the hypothesis in men with prostate cancer.

Despite negative results of castration in two men with prostate cancer reported by [Young \(1936\)](#), a series of 21 consecutive patients with locally advanced or metastatic prostate cancer underwent surgical castration at the University of Chicago. “A noticeable improvement occurred in the clinical status of all but three patients” with weight gain, resolution of anemia, and improvement in pain ([Huggins et al, 1941](#)). Other reported consequences of castration—a large appetite for food, loss of sexual desire and penile erections,

and hot flashes—remain the common side effect profile of androgen ablation therapy today. **Although this report was first to describe the benefits of androgen ablation in the treatment of prostate cancer, it also created a new disease state, castration-resistant prostate cancer.**

In considering these “failure cases” ([Huggins, 1942](#)), it was found that those men with small testes at time of castration had a poor prognosis, the first description of a more ominous prostate cancer arising in the hypogonadal man. Following castration, increases in the levels of urinary 17-ketosteroids, major metabolites of the adrenal gland, led to the hypothesis that adrenal androgens contributed to subsequent disease progression. The first reports of bilateral adrenalectomies for the treatment of castration-resistant disease ([Huggins and Scott, 1945](#)) are described later in a somewhat defensive manner ([Scott, 1954](#)), perhaps because of the lack of response and high perioperative mortality. Hypophysectomy and pituitary irradiation ([Murphy and Schwiippert, 1951](#)) were also investigated. Unfortunately, the benefits of surgical castration were soon equaled by the tenacity and inevitable progression of castration resistance, a state still synonymous with the lethal form of the disease. Even in accepting the 1966 Nobel Prize for this work, Charles Huggins admitted “Despite regressions of great magnitude, it is obvious that there are many failures of endocrine therapy to control the disease” ([Huggins, 1972](#)).

Direct ablation of the source of androgen, like surgical castration, is only one of the perturbations of the hypothalamic-pituitary-gonadal axis developed to treat prostate cancer. **The first central inhibition of the axis exploited the potent negative feedback of estrogen on luteinizing hormone (LH) secretion: estradiol is a thousandfold more potent at suppressing LH and follicle-stimulating hormone (FSH) secretion by the pituitary compared with testosterone (Swerdlloff and Walsh, 1973).** The effects of estrogen on the male phenotype, namely regression of androgen-sensitive tissues, have been exploited historically to produce the effects of castration without surgical removal of the testes. For example, capons (neutered roosters) were produced by placing estrogen pellets in the necks of the birds rather than by castration ([Scott, 1954](#)). Among the various estrogenic compounds, diethylstilbestrol (DES) has been most widely studied and used. Early studies indicating improved survival in men treated with both surgical castration and continuous DES ([Nesbit and Baum, 1951](#)) have not held up under further scrutiny, but the equivalence of DES compared to castration has. Indeed, given the effectiveness of the considerably less expensive estrogenic compounds, it is unfortunate that the associated cardiovascular toxicity has limited their widespread use.

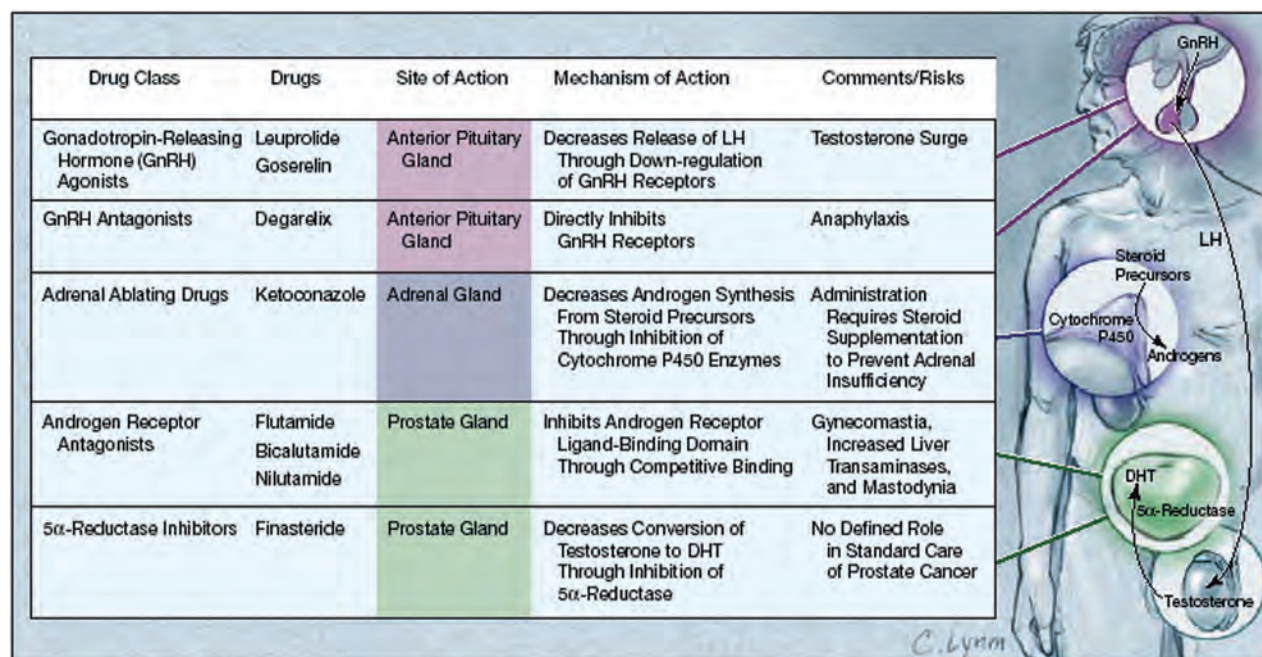

Figure 120-1. Hormonal interventions and endocrine axis in prostate cancer. DHT, dihydrotestosterone; LH, luteinizing hormone. (From Sharifi N, Gulley JL, Dahut WL. Androgen deprivation therapy for prostate cancer. *JAMA* 2005;294:238–44.)

The first isolation of luteinizing hormone-releasing hormone (LHRH) by Andrew Schally and colleagues required the hypothalami of 165,000 pigs to obtain 800 μ g of the 10–amino acid peptide (Schally et al, 1971; Schally, 1992). This 1977 Nobel prize–winning work led to the development of synthetic LHRH analogues, peptides generated by substituting D-amino acid residues at certain locations in the natural compound, creating both LHRH agonists and LHRH antagonists. After an initial surge in LH release (and testosterone levels) in response to LHRH agonists, the loss of phasic pituitary stimulation results in plummeting LH levels. In the absence of LH, Leydig cell production of testosterone drops to castrate levels. Initially, the clinical utility of these agents was hampered by their short half-life, requiring daily injections to maintain suppression of the hypothalamic-pituitary axis. The generation of long-acting depot preparations, lasting several months, has established LHRH agonists as the dominant treatment in hormone therapy for prostate cancer. Recently, direct LHRH antagonists have been developed for clinical use. Lacking agonist action, these agents do not produce the surge in LH and testosterone. It is interesting that both classes of compounds were developed within a few years of the discovery of LHRH and yet it took decades to develop clinically useful agents.

Moving beyond strategies targeting the hypothalamic-pituitary axis, interruption of ligand-receptor interaction with antiandrogenic compounds is another way to reduce androgen action in prostate cancer. All antiandrogens inhibit androgen action by binding to the androgen receptor (AR) in a competitive fashion, and are classified as either steroidal or nonsteroidal. The steroidal antiandrogen cyproterone acetate is a derivative of 17-hydroxyprogesterone and suppresses LH release (and testosterone production) through its central progestational inhibitory effects. Therefore steroidal antiandrogens block androgen action at the cellular level and also reduce circulating testosterone levels, leading to the classic side effects of the hypogonadal state such as loss of libido and erectile dysfunction. On the other hand, the nonsteroidal antiandrogens have no antigonadotropic effects and simply block ARs, including those in the hypothalamic-pituitary axis. By blocking the normal inhibiting feedback of testosterone, the antiandrogens produce a paradoxical increase in LH and testosterone. Although this maintenance of testosterone

can preserve potency in some men, the peripheral conversion of this excessive testosterone to estrogen can lead to painful gynecomastia.

MOLECULAR BIOLOGY OF ANDROGEN AXIS

The AR is a member of the nuclear receptor superfamily, which includes receptors for the sex steroids (androgen, estrogen, progesterone), adrenal steroids (mineralocorticoids, glucocorticoids), thyroid hormones, vitamin D, and retinoids. These receptors act as ligand-inducible transcription factors—meaning they cause transcription of target genes within specific cells after ligands (e.g., testosterone) bind to them. All current forms of androgen deprivation therapy (ADT) function by reducing the ability of androgen to activate ARs, whether through lowering levels of androgen or by blocking androgen-AR binding (Fig. 120-1). Therefore ARs are not directly affected by ADT, leading many to hypothesize that castration-resistant prostate cancer is a result of reactivation of AR-mediated pathways.

A variety of molecular mechanisms are implicated in this process of castration resistance (Fig. 120-2). First, the AR pathway can become hypersensitive through a variety of molecular alterations and be activated by even lower levels of androgen (Linja and Visakorpi, 2004). In castration-resistant tumors, approximately one third of patients will show evidence of AR gene amplification—meaning many more copies of the AR gene are present (Koivisto et al, 1997; Linja et al, 2001). Second, the promiscuity of the AR for ligands other than androgen has been widely recognized. Mutations of the AR gene can also increase receptor activity (Tilley et al, 1996; Gottlieb et al, 1998; Taplin et al, 1999; Marcelli et al, 2000; Balk, 2002). Third, in an outlaw AR model, growth factor peptides such as epidermal growth factor and insulin-like growth factor-1 increase AR transcriptional activity in the absence of androgen (Culig et al, 1994). The cytokine interleukin-6 can activate ARs, as can protein kinases A and C (Nazareth and Weigel, 1996; Lin et al, 2001). If these ligands can reactivate AR signaling in the absence of androgen, then prostate cancer can still progress in the castrate state. Increased expression of AR coregulators, proteins involved in the complex that binds to DNA, has been found in hormone-refractory

Figure 120-2. Five possible pathways (a to e) to castration resistance. AR, androgen receptor; DHT, dihydrotestosterone; MAPK, mitogen-activated protein kinase; P, phosphorylated; PSA, prostate-specific antigen; RTK, receptor tyrosine kinase. (From Feldman BJ, Feldman D. The development of androgen-independent prostate cancer. *Nat Rev Cancer* 2001;1:34–45.)

prostate cancer, suggesting autonomous activation of the pathway (Yeh et al, 1999; Fujimoto et al, 2001; Gregory et al, 2001). Fourth, in a bypass AR model, activation of parallel or alternative survival pathways allows otherwise androgen-dependent prostate cancer cells to survive in the absence of androgen (Feldman and Feldman, 2001). Finally, in a lurker cell model, a small population of possible epithelial stem cells is preexistent in the prostate and androgen deprivation selects for the outgrowth of these castration-resistant cells. Rather than an acquired alteration, this model suggests an inherent quality of the prostate gland.

Even when prostate cancer progresses despite castrate levels of androgen, it is rarely resistant to androgen action. In 87% of patients with castration-resistant prostate cancer, the administration of exogenous androgen results in symptomatic tumor flare (Fowler and Whitmore, 1982). Therefore the term *androgen independent* is not completely precise: such a cancer is no longer dependent on androgen (and thus may be considered independent), but since it remains responsive to androgen it is not wholly independent of the influence of androgen. The term *androgen refractory* indicates a disease state wherein the cancer is able to progress in the absence of androgen, but is definition-neutral about a responsiveness to androgen. Likewise, the word “hormone” is quite broad and includes the host factors defining the field of endocrinology. Therefore the term *hormone independent* is vague: as evident from the

therapeutic response to secondary hormonal manipulation (estrogens and glucocorticoids), androgen-refractory prostate cancer is not actually independent of hormone action. The terms *hormone independent* and *hormone refractory* should be reserved for the rare cancers that are completely nonresponsive to any hormonal agent (Chang et al, 2005). Although the term *hormone-refractory prostate cancer* has been widely used to describe a state of progressive disease despite ADT, the term *castration-resistant prostate cancer* is more clinically precise and relevant (Scher et al, 2004, 2008b).

SOURCES OF ANDROGEN

Testosterone is the major circulating androgen, with 90% produced by the testes. Over half of testosterone is bound to sex hormone-binding globulin and 40% is bound to albumin. Only 3% of testosterone remains unbound and this is the functionally active form of the hormone. Following passive diffusion through the cell membrane into the cytoplasm, testosterone undergoes conversion to dihydrotestosterone (DHT) through the action of the enzyme 5α-reductase. Although the relative potency of testosterone and DHT are similar (as defined by the ability to cause half-maximal response in a prostate regrowth model), if the conversion of testosterone to DHT is blocked by the 5α-reductase inhibitor finasteride,

TABLE 120-1 Major Circulating Androgens

SOURCE	ANDROGEN	AMOUNT PRODUCED/DAY (mg)	RELATIVE POTENCY	RELATIVE POTENCY/AMOUNT PRODUCED
Testes	Testosterone	6.6	100	15.2
Testes and peripheral tissues	Dihydrotestosterone	0.3	160-190	533-633
Adrenal glands	Androstenedione	1.4	39	27.9
Adrenal glands	Dehydroepiandrosterone	29	15	0.5

13-fold more testosterone is required for the same effect (Wright et al, 1999). Both testosterone and DHT exert their biologic effects by binding to the AR in the cytoplasm, promoting the association of AR coregulators. The complex then translocates to the nucleus and binds to androgen response elements in the promoter regions of target genes (Heinlein and Chang, 2004).

Androgens produced by the adrenal gland—androstenedione and dehydroepiandrosterone—are stimulated by adrenocorticotrophic hormone (ACTH) released by the pituitary gland in response to corticotropin-releasing factor. Adrenal androgens negatively feed back on ACTH secretion: cortisol acts as the feedback signal. **Adrenal androgens are relatively weak compared to testosterone and DHT and are almost entirely bound to albumin (Table 120-1).** Adrenal androgens remain normal in men who have undergone orchiectomy (Walsh and Siiteri, 1975) and are insufficient to maintain prostatic epithelium in such men.

MECHANISMS OF ANDROGEN AXIS BLOCKADE

Four therapeutic approaches for androgen axis blockade are in current clinical use: (1) ablation of androgen sources, (2) antiandrogens, (3) inhibition of LHRH and/or LH release, and (4) inhibition of androgen synthesis (Box 120-1).

Ablation of Androgen Sources

Bilateral orchiectomy quickly reduces circulating testosterone levels to less than 50 ng/dL, which is considered the castrate range. Within 24 hours of surgical castration, testosterone levels are reduced by greater than 90% (Maatman et al, 1985). The Veterans Administration Cooperative Urological Research Group (VACURG) conducted a series of larger clinical trials demonstrating the clinical effectiveness of surgical castration in reducing pain and improving performance status in men with advanced disease (VACURG, 1967a, 1967b; Byar, 1973; Byar and Corle, 1988). Subcapsular orchiectomy has been advocated as a technique of ADT that avoids the psychological consequences of an empty scrotum (Desmond et al, 1988). Because this approach relies on the complete removal of all intratesticular tissue and Leydig cells, it is more dependent on technique than a simple orchiectomy to achieve ADT. In a properly performed operation, however, the hormonal and cancer responses are indistinguishable from a simple, complete orchiectomy (Zhang et al, 1996).

Antiandrogens

Cyproterone Acetate

The classic steroidal antiandrogen with direct AR blocking effects, cyproterone acetate also rapidly lowers testosterone levels to 70% to 80% through its progestational central inhibition (Jacobi et al, 1980; Goldenberg and Bruchovsky, 1991; Barradell and Faulds, 1994). An oral agent, the recommended dose is 100 mg two to three times per day. Side effects are consistent with the hypogonadal state and include loss of libido, erectile dysfunction, and lassitude. Severe cardiovascular complications can occur in up to

Histrelin
Cetorelix
Abarelix
Degarelix

INHIBITION OF ANDROGEN SYNTHESIS

Aminoglutethimide
Ketoconazole
Abiraterone

*Several agents have multiple sites of action.

10% of patients, limiting the use of cyproterone acetate (de Voogt et al, 1986). Gynecomastia occurs in less than 20% of men. Rare cases of fulminant hepatotoxicity have been reported (Parys et al, 1991). It has been used at doses of 50 to 100 mg/day for the treatment of hot flashes (Goldenberg and Bruchovsky, 1991).

Nonsteroidal Antiandrogens

By blocking the testosterone feedback centrally, the nonsteroidal antiandrogens cause LH and testosterone levels to increase. Testosterone levels reach about 1.5 times the normal levels of hormonally intact men (Neri, 1977). This allows antiandrogen activity without inducing hypogonadism: potency therefore can be preserved (Brufsky et al, 1997). However, in clinical trials specifically examining erectile functioning and sexual activity in men on flutamide monotherapy, long-term preservation of those domains was only 20%, not much different than men undergoing surgical castration (Schröder et al, 2000). The peripheral aromatization of increased testosterone to estradiol has been demonstrated after antiandrogen administration (Knuth et al, 1984), leading to the widely recognized gynecomastia and mastodynia associated with these

agents. Gastrointestinal toxicity, and most notably diarrhea, is more common with flutamide than the other nonsteroidal antiandrogens (Han and Nelson, 2000). Liver toxicity, ranging from reversible hepatitis to fulminant hepatic failure, is associated with all nonsteroidal antiandrogens and requires periodic monitoring of liver function tests (Lund and Rasmussen, 1988; Wysowski et al, 1993; Dawson et al, 1997; Thole et al, 2004).

Flutamide. A nonsteroidal antiandrogen, flutamide was the first “pure” antiandrogen (Neri et al, 1967). Because of the short half-life (6 hours) of the active metabolite, 2-hydroxyflutamide, this oral agent must be given three times a day at 250 mg per dose. Elimination of hydroxyflutamide is via renal excretion. Unlike the steroidal antiandrogens, there are no associated side effects of fluid retention or thromboembolism (Delaere and Van Thillo, 1991). In a randomized, double-blind study comparing flutamide to DES (3 mg/day) in metastatic prostate cancer, overall survival was significantly shorter with flutamide (28.5 months) compared to DES (43.2 months) (Chang et al, 1996).

Bicalutamide. A nonsteroidal antiandrogen with a long serum half-life (6 days), bicalutamide has a once-per-day dosing schedule and therefore likely better compliance. It is the most potent of the “first-generation” nonsteroidal antiandrogens (Kolvenbag and Nash, 1999) and the best tolerated (Kolvenbag and Blackledge, 1996; Fradet, 2004; Schellhammer and Davis, 2004). The pharmacokinetics of bicalutamide are not affected by age, renal insufficiency, or moderate hepatic impairment (Mahler et al, 1998). The R-isomer of bicalutamide has about a 30-fold higher binding affinity for the AR compared to the S-isomer and functionally processes the antiandrogen activity (Mukherjee et al, 1996). As with the other antiandrogens, bicalutamide is associated with maintenance of serum testosterone levels: in the majority of patients, these remain within the normal range (Denis and Mahler, 1996; Tay et al, 2004).

Bicalutamide as monotherapy has been most extensively studied and, as with flutamide monotherapy's inferiority to DES, bicalutamide monotherapy at a 50-mg/day dose was inferior to castration in survival of men with metastatic disease (Kaisary et al, 1995; Bales and Chodak, 1996; Kolvenbag and Nash, 1999). At a higher dose of 150 mg/day, however, bicalutamide monotherapy appears to have equivalent efficacy to medical or surgical castration (Tyrrell et al, 1998; Iversen et al, 2000; Anderson, 2003; Iversen, 2004; Iversen et al, 2004; Wirth et al, 2004, 2005; McLeod et al, 2006) in men with metastatic or locally advanced disease. In these large phase III studies, bicalutamide monotherapy (150 mg/day) had significantly better quality of life in the domains of sexual interest and physical capacity (Iversen, 2003). There was, however, a high rate of gynecomastia (66.2%) and breast pain (72.8%) (Iversen, 2003). More concerning, in men with low-risk, localized prostate cancer, bicalutamide was associated with significantly worse overall survival compared to watchful waiting (see later).

Nilutamide. The plasma half-life of nilutamide is 56 hours, and elimination is via hepatic clearance employing the cytochrome P450 system. Because steady-state plasma levels are achieved in 14 days on once-per-day dosing (Creaven et al, 1991), dosing recommendations are a single 300-mg daily dose for the first month of treatment followed by a single 150-mg daily dose (Mahler et al, 1998). About one quarter of men on nilutamide therapy will note a delayed adaptation to darkness after exposure to bright illumination (Creaven et al, 1991). Nilutamide is also associated with interstitial pneumonitis in approximately 1% of patients that can progress to pulmonary fibrosis (Pfizenmeyer et al, 1992). The early effects are usually reversible with cessation of nilutamide. In a small study, there was a suggestion of a role for nilutamide as an effective secondary hormonal agent (Desai et al, 2001).

Enzalutamide. This small molecule is an AR antagonist, but unlike bicalutamide, enzalutamide inhibits AR function by blocking nuclear translocation and DNA binding and has no agonist activity when AR is overexpressed (Tran et al, 2009). Early clinical trials with enzalutamide demonstrated prostate-specific antigen (PSA) declines in the majority of patients with castration-resistant prostate cancer (Scher et al, 2008a). A phase III clinical trial of enzalutamide in men with metastatic, castration-resistant prostate cancer who had

Overall survival

Figure 120-3. Overall survival among patients with metastatic, castration-resistant prostate cancer after receiving enzalutamide compared to patients receiving placebo after previous treatment with chemotherapy. CI, confidence interval. (From Scher HI, Fizazi K, Saad F, et al; AFFIRM Investigators. Increased survival with enzalutamide in prostate cancer after chemotherapy. *N Engl J Med* 2012; 367: 1187-97.)

failed docetaxel chemotherapy showed significant improvements in overall survival and radiographic progression-free survival (Scher et al, 2012) (Fig. 120-3). Likewise, another phase III clinical trial of enzalutamide in men with metastatic castration-resistant prostate cancer who had not received chemotherapy also showed significant improvements in overall survival and radiographic progression-free survival (Beer et al, 2014). The most common side effects of enzalutamide are fatigue, diarrhea, and hot flashes. Seizures occurred in clinical trials of this agent, but in less than 1% of patients.

Antiandrogen Withdrawal Phenomenon

Patients treated with a combination of an antiandrogen and an LHRH agonist can experience a decline in PSA and even in objective responses with the withdrawal of the antiandrogen from the combination. Based on this response, it appears that the antiandrogen is actually exerting agonistic activity on prostate cancer cells. This phenomenon, first described with flutamide (Kelly and Scher, 1993), has now been demonstrated with all antiandrogens, including cyproterone acetate, as well as with DES and progestational agents (Kelly et al, 1997). Declines in PSA are seen within 4 weeks with flutamide withdrawal and within 6 weeks with bicalutamide and nilutamide withdrawal (Nieh, 1995). Between 15% and 30% of patients may have PSA declines of greater than 50% after antiandrogen withdrawal, and the declines have a median duration of 3.5 to 5 months (Scher and Kelly, 1993; Small and Srinivas, 1995). Objective, measurable tumor responses are observed less commonly. Overall survival has not been shown to be increased in those patients demonstrating the antiandrogen withdrawal phenomenon compared to those who have not (Small and Srinivas, 1995). Clinical trial designs of novel agents must take this phenomenon into consideration, given the possible confounding effects (Scher and Kelly, 1993). Prospective criteria to predict who will demonstrate this response have not been established, but it has been recognized that those with rapid PSA responses following androgen ablation have higher rates of antiandrogen withdrawal phenomenon.

It has been postulated that mutations in the AR gene may underlie this phenomenon, allowing the antiandrogen to behave as an activator of the AR (Taplin et al, 1995). The widely used prostate cancer cell line LNCaP expresses an AR with a specific point mutation that causes cell proliferation in the presence of

hydroxyflutamide; the identical mutation was found in human tumor samples from patients who had remarkable PSA declines after antiandrogen withdrawal (Suzuki et al, 1996). Similar point mutations in the AR have been described for bicalutamide to act as an agonist (Hara et al, 2003), with the structural basis of this mutation resolved by x-ray crystallography demonstrating the ability of bicalutamide to bind to the mutant AR in a fashion similar to DHT binding to the wild-type AR (Bohl et al, 2005).

Inhibition of Luteinizing Hormone–Releasing Hormone

Luteinizing Hormone–Releasing Hormone Agonists

The LHRH agonists exploit the desensitization of LHRH receptors in the anterior pituitary following chronic exposure to LHRH, thereby shutting down the production of LH and, ultimately, testosterone. The clinical utility of the current LHRH agonists is based on the creation of LHRH analogues by amino acid substitutions, particularly position 6 in the peptide, increasing their potency and half-lives. Pharmacologic depot preparations and osmotic pump devices allow dosing to extend from 28 days to 1 year, respectively (Ahmann et al, 1987). In a review of 24 trials involving more than 6600 patients, survival after therapy with an LHRH agonist was equivalent to that after orchiectomy (Seidenfeld et al, 2000).

The initial exposure to more potent agonists of LHRH results in a flare of LH and testosterone levels (Waxman et al, 1985). This phenomenon is seen with all available LHRH preparations and can result in a severe, life-threatening exacerbation of symptoms. The flare, associated with up to a 10-fold increase in LH, may last for 10 to 20 days (Weckermann and Harzmann, 2004). Fortunately, the coadministration of an antiandrogen functionally blocks the increased levels of testosterone (Labrie et al, 1987; Kuhn et al, 1989; Schulze and Senge, 1990). Although it had been argued that the administration of the antiandrogen should precede the administration of the LHRH agonist by a week, others have found no differences in PSA levels with the simultaneous administration of both agents (Tsushima et al, 2001). Given the predictable length of the flare phenomenon, antiandrogen coadministration is required for only 21 to 28 days.

Luteinizing Hormone–Releasing Hormone Antagonists

The LHRH antagonists bind immediately and competitively to the LHRH receptors in the pituitary, reducing LH concentrations by 84% within 24 hours of administration (Weckermann and Harzmann, 2004). The direct antagonistic activity eliminates the LH and testosterone flare, which is the major therapeutic advantage of these agents: there is no need for antiandrogen coadministration. Hormonally naive patients with impending spinal cord compression or severe bone pain for whom surgical castration is not appropriate may uniquely benefit from this class of agents: clinical response has been observed with the LHRH antagonist cetrorelix (Gonzalez-Barcena et al, 1995).

In clinical trials of the LHRH antagonist abarelix, testosterone levels dropped very quickly, with 34.5%, 60.5%, and 98.1% of men chemically castrate at 2, 4, and 28 days, respectively (Tomera et al, 2001). Compared to an LHRH agonist and an antiandrogen, abarelix monotherapy was equally effective in achieving castrate levels of testosterone (Trachtenberg et al, 2002). Ninety-percent of men with symptomatic prostate cancer treated in an open-label fashion had improvements in pain and/or disease-related problems (Koch et al, 2003).

Many of the first- and second-generation antagonists induced significant histamine-mediated side effects, complications not as often observed in third- and fourth-generation agents (Weckermann and Harzmann, 2004). Nevertheless, severe allergic reactions can occur with abarelix, even after previously uneventful treatment (Koch et al, 2003). Abarelix is approved in the United States for the treatment of advanced prostate cancer in patients who cannot take other hormonal therapies and have refused surgical castration.

Given the rare but serious allergic reactions, patients must be monitored for at least 30 minutes after administration.

FSH levels are only partially suppressed by LHRH agonists and are significantly elevated after surgical castration given the loss of inhibitory feedback. LHRH antagonists reduce both LH and FSH levels. In an androgen-insensitive prostate cancer xenograft model, cetrorelix significantly reduced tumor growth (Lamharzi et al, 1998), suggesting other factors stimulate tumor growth. In men with disease progression following surgical castration, treatment with abarelix reduced FSH levels by nearly 90% but did not meet criteria for PSA response (Beer et al, 2004a).

Unlike abarelix, the LHRH antagonist degarelix has no systemic allergic reactions, (Gittelman et al, 2008; Klotz et al, 2008). In a phase III study, degarelix was compared to leuprolide: at 1 year of treatment degarelix was not inferior to leuprolide, and based on this result it has been approved for use in the United States.

Inhibition of Androgen Synthesis

Aminoglutethimide

Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone, an early step in steroidogenesis (Cash et al, 1967; Blankenstein and Bakker, 1985). Given its inhibition of a very proximal step in adrenal function, aminoglutethimide blocks production of aldosterone and cortisol. As the medical version of a total adrenalectomy, the use of this agent requires replacement of cortisone and fludrocortisone. Side effects include anorexia, nausea, skin rash, lethargy, vertigo, hypothyroidism, and nystagmus. Clinical responses have been observed in a subset of patients with androgen-refractory prostate cancer treated with aminoglutethimide plus cortisone (Sanford et al, 1976; Ponder et al, 1984). In the PSA era, treatment with aminoglutethimide (1000 mg/day) and hydrocortisone acetate (40 mg/day) resulted in a greater than 50% decline in PSA in 37% of patients, with median response times lasting 9 months (Kruit et al, 2004).

Ketoconazole

An orally active, broad-spectrum azole antifungal agent, ketoconazole interferes with two cytochrome P450–dependent pathways: by inhibiting 14-methylation it blocks the conversion of lanosterol to cholesterol, and it also blocks 17,20-desmolase, impacting on the conversion of C₂₁ to C₁₉ steroids. Based on the observation that some patients taking the drug developed gynecomastia, investigations of its effects on steroid synthesis demonstrated loss of adrenal steroid synthesis (Pont et al, 1982b) and testosterone synthesis by Leydig cells (Pont et al, 1982a). The effects were rapid, with testosterone levels dropping to the castrate level with 4 hours of administration in some cases (Trachtenberg et al, 1983). The effects were also immediately reversible, indicating dosing must be continuous (400 mg every 8 hours) to maintain low testosterone levels.

Early experience with ketoconazole in the treatment of prostate cancer showed this agent to be tolerable, durable, and effective (Trachtenberg and Pont, 1984) and it was palliative for those who had failed first-line androgen ablation therapy (Pont, 1987). Although ketoconazole is effective in rapidly bringing testosterone levels into the castrate range, with continuous treatment in the otherwise hormonally intact individual (no other surgical or chemical ADT), testosterone levels begin to rise and can reach low-normal ranges within 5 months of therapy (Vanuytsel et al, 1987). Therefore currently ketoconazole is used for men with castration-resistant prostate cancer, often as the first or second agent in so-called secondary hormonal manipulation (Small et al, 2004). In addition to gynecomastia (caused by alterations in testosterone/estradiol ratios [Pont et al, 1985]), ketoconazole is associated with lethargy, weakness, hepatic dysfunction, visual disturbance, and nausea (Wilkinson and Chodak, 2004; Scholz et al, 2005). Because of the adrenal suppression, ketoconazole is usually given with hydrocortisone (20 mg twice per day). Patients with higher levels of the adrenal androgen androstenedione had an improved survival

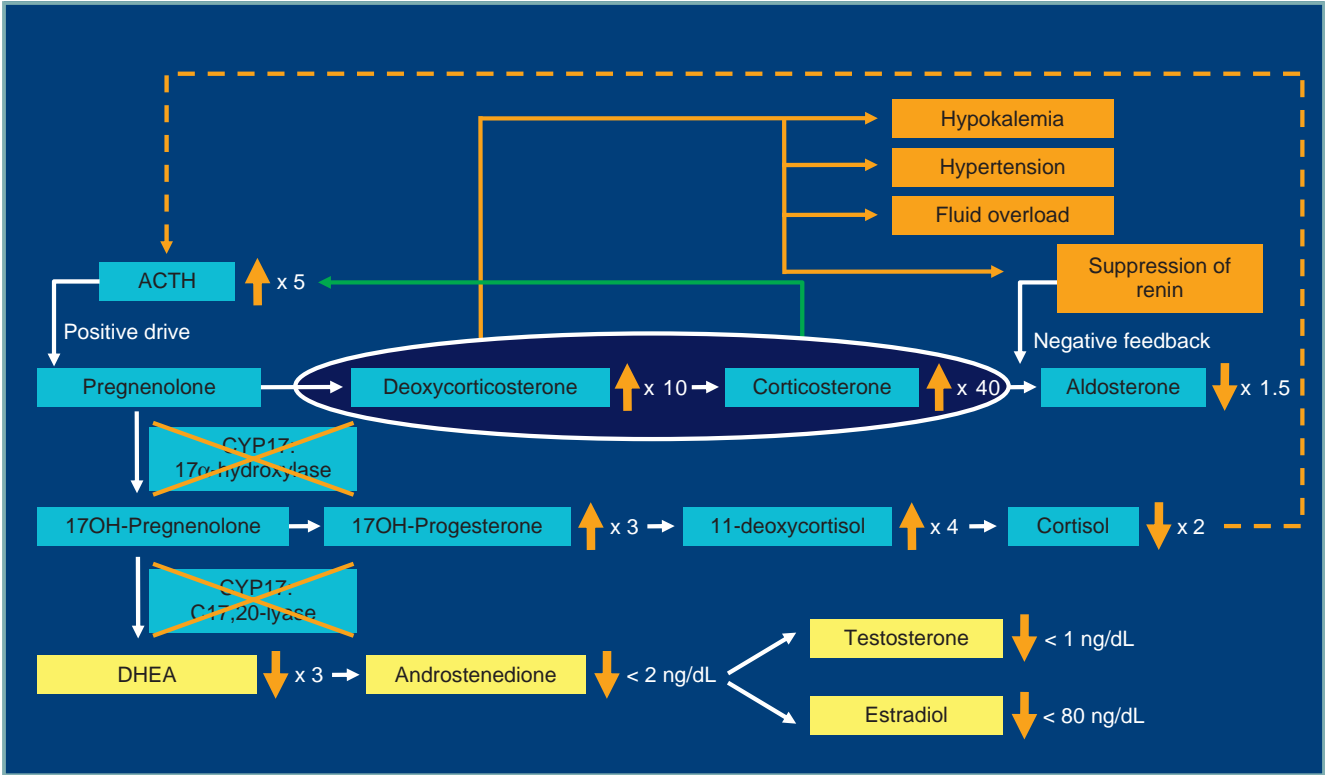

Figure 120-4. Mechanism of action of abiraterone, and potential side effects. ACTH, adrenocorticotropic hormone. (Modified from Attard G, Reid AH, Yap TA, et al. Phase I clinical trial of a selective inhibitor of CYP17, abiraterone acetate, confirms that castration-resistant prostate cancer commonly remains hormone driven. *J Clin Oncol* 2008;26:4563–71.)

in response to ketoconazole compared to those with lower levels, suggesting that ketoconazole is less effective in patients with low levels of androgen at baseline (Ryan et al, 2007).

Abiraterone

Unlike the less potent ketoconazole, which inhibits several cytochrome P pathways, abiraterone is a potent, selective, and irreversible inhibitor of cytochrome P17, a key enzyme in androgen synthesis (Chan et al, 1996). Specifically, abiraterone inhibits 17α-hydroxylase, resulting in excess synthesis of aldosterone and its precursors and causing a suppression of cortisol with a compensatory rise in ACTH. Abiraterone also inhibits C_{17,20}-lyase, resulting in suppression of testosterone to levels of less than 1 ng/mL (significantly lower than castrate levels of 50 ng/mL) (O'Donnell et al, 2004; Attard et al, 2005). Abiraterone was developed based on the hypothesis that castration-resistant prostate cancer remains driven by low levels of androgens. Although abiraterone is generally well tolerated, toxicities stem from the effects of blocking the conversion of pregnenolone to 17-hydroxypregnenolone, resulting in an increase in the mineralocorticoids deoxycorticosterone and corticosterone (Fig. 120-4). Untreated, this can result in hypokalemia, hypertension, and fluid overload (Attard et al, 2008). Coadministration of prednisone suppresses the increases in ACTH resulting from decreases in cortisol and mineralocorticoid excess. In men with metastatic castration-resistant prostate cancer after treatment with docetaxel, abiraterone plus prednisone significantly improved overall survival and progression-free survival compared to placebo plus prednisone (Fig. 120-5). Declines in PSA and radiographic responses occurred in 29% and 14% of men on abiraterone, respectively (de Bono et al, 2011). Similarly, in men with metastatic castration-resistant prostate cancer prior to chemotherapy, abiraterone plus prednisone significantly improved progression-free

Figure 120-5. Overall survival among patients with metastatic, castration-resistant prostate cancer after receiving abiraterone plus prednisone compared to patients receiving placebo plus prednisone after previous treatment with chemotherapy. (From de Bono JS, Logothetis CJ, Molina A, et al; COU-AA-301 Investigators. Abiraterone and increased survival in metastatic prostate cancer. *N Engl J Med* 2011;364:1995–2005.)

survival and overall survival compared to placebo plus prednisone (Fig. 120-6) (Ryan et al, 2013).

RESPONSE TO ANDROGEN BLOCKADE

Following the initiation of ADT, the vast majority of prostate cancer patients will show some evidence of clinical response: the magnitude and rapidity of that response remain the best predictors of its durability. Assuming ADT effectively targets the androgen-sensitive population of prostate cancer cells, an incomplete or sluggish response is evidence of a significant androgen-refractory cell population. Early in the clinical use of PSA as a biomarker of prostate cancer, it was recognized that declines in PSA could predict response (Hudson et al, 1989; Aria et al, 1990; Cooper et al, 1990). For example, patients who had more than an 80% drop in PSA within 1 month of initiating ADT survived significantly longer free of disease progression (Aria et al, 1990). Likewise, the nadir PSA predicted the progression-free interval (Matzkin et al, 1992; Benaim et al, 2002a), as did pretreatment testosterone levels (Imamoto et al, 2001). A rise in PSA, evidence of the emergence of castration-resistant disease, preceded bone metastatic progression by several months, with a mean lead time of 7.3 months (Cooper et al, 1990; Miller et al, 1992).

More recent studies of PSA response to ADT have confirmed and amplified those observations. The odds ratio for progressing to castration-resistant disease within 24 months of starting ADT was almost 15 times higher for patients who did not achieve an undetectable PSA (Benaim et al, 2002a). For each unit increase in Gleason score, the cumulative hazard of castration-resistant progression was nearly 70% (Benaim et al, 2002b). In one cohort of Asian men, nadir PSA was the most accurate predictor of disease progression and was independently prognostic of survival; achieving a PSA level of 1.1 ng/mL or less at 6 months after initiating ADT was the most sensitive and specific predictor of progression at 2 years (Kwak et al, 2002). In men with newly diagnosed metastatic prostate cancer (stage D2) started on ADT, the absolute PSA level after 7 months of ADT was a strong, independent predictor of survival (Hussain et al, 2006). Median survival of men achieving a PSA of 0.2 ng/mL or less was 75 months, compared to 13 months for men whose nadir was greater than 4 ng/mL. The kinetics of PSA rise prior to ADT compared to the rate of PSA decline after ADT also

predicted outcome, specifically prostate cancer-specific mortality (D'Amico et al, 2005). If the pre-ADT PSA rise was rapid and the decline after ADT was slow, the cancer-specific mortality was significantly worse compared to that in patients with slow rises of PSA pre-ADT and rapid declines after ADT (D'Amico et al, 2004b).

Almost without exception, those men no longer responding to ADT (androgen-refractory) remain on ADT. Therefore factors influencing survival in that disease state should be considered in this discussion. In most cases available data are based on pre- or post-treatment responses to other systemic treatments (Galsky and Kelly, 2003). Consistently predictive variables (by both univariate and multivariate analysis) of survival in this state include performance status, serum lactate dehydrogenase, serum alkaline phosphatase, hemoglobin, and PSA response to secondary therapy (Smaletz et al, 2002). The survival of men treated on seven sequential chemotherapy protocols at one institution provided an early experience in developing predictive measures (Kelly et al, 1993). A 50% decline in PSA in response to chemotherapy was one of the most significant variables predicting survival. A nomogram based on a larger group of patients found that the presence of visceral disease, Gleason score, performance status, and baseline PSA, lactate dehydrogenase, alkaline phosphatase, and hemoglobin were useful in modeling prognosis (Smaletz et al, 2002; Halabi et al, 2003).

GENERAL COMPLICATIONS OF ANDROGEN ABLATION

Osteoporosis

The increased number of men being placed on androgen ablation therapy much earlier in the course of their disease allows the chronic manifestations of the hypogonadal state to emerge. Widespread androgen ablation therapy applied to an increasing aging population, already predisposed to loss of bone mineral density (BMD), has created an epidemic of osteopenia and osteoporosis. Fragile bones increase the risk of skeletal fracture. More than half of men meet the BMD criteria for osteopenia or osteoporosis—defined as more than 2.5 standard deviations below an age-specific reference mean—prior to the initiation of ADT (Wei et al, 1999; Conde et al, 2004). The longer a man remains on ADT, the greater the risk of fracture (Daniell et al, 2000; Krupski et al, 2004). After 5 years on ADT, 19.4% of men experienced fractures compared to 12.6% of controls (Shahinian et al, 2005); over 15 years the

cumulative incidence of fractures was 40% compared to 19% in noncastrate controls (Melton et al, 2003). It has been estimated that 4 years of ADT will place the average man in the osteopenia range (Wei et al, 1999). Prostate cancer was associated with an increased odds ratio for hip fractures of 3.7 (95% confidence interval [CI] 3.1 to 4.4) in a large Danish population-based study (Abrahamsen et al, 2007). Rarely discussed even 10 years ago, skeletal health is now becoming a major concern of patients and their physicians (Chen et al, 2002).

Treatment of osteoporosis begins with recognition. BMD of the hip as measured by dual-energy x-ray absorptiometry should be considered for all men who are anticipated to be on long-term ADT (Bae and Stein, 2004; Diamond et al, 2004). Smoking cessation, weight-bearing exercise, and vitamin D and calcium supplementation can help improve BMD. **Daily supplementation of calcium and vitamin D is recommended by the National Institutes of Health at doses of 1200 to 1500 mg/day and 400 IU/day, respectively** (Michaelson et al, 2008). Supplementation decreases the incidence of nonvertebral fractures in men and women over 65 years of age (Dawson-Hughes et al, 1997). Prevention of osteoporosis in men receiving ADT has been demonstrated in controlled studies using the bisphosphonate pamidronate (Smith et al, 2001). **In a randomized prospective study, once-weekly oral alendronate reversed bone loss associated with ADT and improved bone density; this benefit continued with ongoing treatment, suggesting chronic treatment is beneficial** (Greenspan et al, 2007, 2008). BMD also increased in men on ADT using the considerably more potent bisphosphonate zoledronic acid (Smith et al, 2003a). Bisphosphonate therapy should be considered in any man with evidence of osteopenia or osteoporosis (Bae and Stein, 2004). Transdermal estradiol also increases BMD in men with prostate cancer (Ockrim et al, 2004). Not surprisingly, serum testosterone and estradiol levels were much lower in men receiving LHRH agonists compared to those on a nonsteroidal antiandrogen; interestingly, markers of bone turnover were significantly higher in men on LHRH agonists compared to those on a nonsteroidal antiandrogen, suggesting the nonsteroidal antiandrogens may help maintain BMD (Smith et al, 2003b).

Hot Flashes

For over 100 years, hot flashes (also called hot flushes or vasomotor symptoms) have been recognized as a side effect of androgen ablation: in 1896, Cabot mentioned “uncomfortable flushes of heat, similar to those experienced by women at the time of menopause” in men undergoing castration for prostatic enlargement (Cabot, 1896; Stearns, 2004). Described as a subjective feeling of warmth in the upper torso and head followed by objective perspiration, hot flashes are not life-threatening but are among the most common side effects of androgen ablation, affecting between half and 80% of patients (Moyad, 2002; Spetz et al, 2003; Nishiyama et al, 2004). Occurring both spontaneously and precipitated by changes in body position, ingestion of hot liquids, or changes in environmental temperature, the exact etiology of hot flashes remains undefined. The proposed mechanisms include increases in hypothalamic adrenergic concentrations and alterations in β -endorphins and calcitonin gene-related peptides acting on the thermoregulatory center in the hypothalamus (Yuzurihara et al, 2003). Hot flashes generally decrease in both frequency and intensity over time but often persist in some men (Holzbeierlein et al, 2004).

Treatment of hot flashes should be reserved for those men who find them bothersome. Just as hot flashes are a consequence of alterations in the hormonal milieu, the mainstay of treatment has been based on efforts to influence that milieu (Kouriefs et al, 2002). In a double-blind, placebo-controlled crossover study, the progestational agent megestrol acetate (20 mg twice per day) significantly reduced the frequency of hot flashes (Loprinzi et al, 1994b). The dose can be reduced to 5 mg twice daily, which may help reduce the appetite-stimulating effect of this agent. The efficacy of cyproterone acetate is based on its progestational effects (Cervenak et al, 2000). Dosing should start at 50 mg/day and be

titrated to 300 mg/day. Estrogenic compounds such as low-dose DES and transdermal estradiol appear to be the most effective treatment, with up to 90% partial or complete resolution of symptoms (Miller and Ahmann, 1992; Smith, 1994; Gerber et al, 2000). With estrogen compounds, however, the cure may be worse than the disease; painful gynecomastia and thromboembolic effects have limited the utility of this approach. Clonidine, a centrally acting α agonist that decreases vascular reactivity, has been used with mixed results: in a placebo-controlled study, transdermal clonidine did not significantly decrease hot flashes (Loprinzi et al, 1994a). Antidepressant agents, particularly the selective serotonin reuptake inhibitor venlafaxine (12.5 mg twice daily), have reduced hot flashes in more than 50% of men (Quella et al, 1999; Loprinzi et al, 2004). In a phase III randomized, double-blind, placebo-controlled trial, the antiseizure agent gabapentin decreased hot flashes to a moderate degree (Loprinzi et al, 2009).

Sexual Dysfunction (Erectile Dysfunction and Loss of Libido)

The effects of ADT on sexual function are profound, as first described by Huggins and colleagues in 1941: “Sexual desire and penile erections were absent in all cases following castration.” **Loss of sexual functioning is not inevitable, however, with up to 20% of men on ADT able to maintain some sexual activity** (Rousseau et al, 1988; Clark et al, 2001). Specifically, between 10% and 17% of men undergoing ADT can maintain an erection adequate for intercourse (Tomić, 1983; Potosky et al, 2001). **Libido is more severely compromised, with approximately 5% of men maintaining a high level of sexual interest with ADT** (Potosky et al, 2001). Sexual desire is inversely related to the duration of androgen deprivation (Basaria et al, 2002). Loss of penile volume and penile length, loss of nocturnal penile tumescence, and, for those undergoing medical ADT, loss of testicular volume are common (Marumo et al, 1999; Higano, 2003).

Treatment for loss of libido is extremely difficult—if not impossible—for those on ADT. Likewise, medical treatments such as oral phosphodiesterase-5 inhibitors or local treatments such as intracavernosal injections of alprostadil can still be effective in selected patients but may not be used over the long term. If there is any fairness in the negative effects of ADT on sexual function, it is the decline in both libido and erectile functioning: despite no erections or desire, the majority of patient have little to no problem with their (lack) of sexual functioning (Potosky et al, 2001).

Cognitive Function

There is a strong suggestion that ADT is linked to subtle but significant cognitive declines in men with prostate cancer (Nelson et al, 2008). In both men and women, the hypogonadal state is associated with declines in cognitive functioning (Gouchie and Kimura, 1991; Sherwin and Tulandi, 1996). Testosterone supplementation improves verbal fluency (Alexander et al, 1998), but other controlled studies have found no effect of such supplementation on memory (Sih et al, 1997). In a small study, men with prostate cancer randomized to ADT performed worse in cognitive studies compared to men with prostate cancer under surveillance (Green et al, 2002); the declines were associated with tasks requiring complex information processing (Green et al, 2004). Compared to tests for other cognitive domains, tests for spatial ability uniquely declined in men on intermittent hormone therapy (Cherrier et al, 2003). In men on neoadjuvant ADT prior to radiotherapy, cognitive functioning declined (Jenkins et al, 2005). Unfortunately, the studies examining the effects of ADT on cognitive functioning have been small and underpowered. Not surprisingly given the many side effects of ADT, quality of life worsens specifically in the domain of emotional functioning in men receiving flutamide in addition to castration compared to placebo (Moynour et al, 1998). A short course of ADT (36 weeks) increased depression and anxiety scores on formal neuropsychological evaluations (Almeida et al, 2004);

major depressive disorder was prevalent in 12.8% of men on ADT, eight times greater than the national rate and 32 times the rate of men over 65 years of age (Pirl et al, 2002). Finally, psychological distress accounted for approximately one third of declines in a fatigue severity scale in men undergoing ADT (Stone et al, 2000).

Changes in Body Habitus

A loss of muscle mass and increase in percent fat body mass are common in men undergoing ADT, and these changes are most pronounced with the initiation of ADT (van Londen et al, 2008). After 1 year of ADT, the mean overall weight increases by 1.8% to 3.8%, which translates into about 5 pounds for a 200-lb man (Berruti et al, 2002; Smith et al, 2002; Smith, 2004). One study found that weight increased a median of 6 kg (13.2 lbs), with a range of 3 to 15 kg (6.6 to 33 lbs) (Higano et al, 1996). Since lean body mass usually decreases by the same magnitude, the weight gain is largely due to an increase in fat mass (Levy et al, 2008). The average increase in fat mass ranges from 9.4% to 23.8% (Berruti et al, 2002; Smith et al, 2002; Smith, 2004). As noted by Huggins and colleagues (1941), ADT is associated with an increase in appetite, and low testosterone is associated with increased insulin levels and abdominal girth (Seidell et al, 1990).

The Cancer Prevention Studies I and II (1959-1972 and 1982-1996, respectively) were large population-based studies of obesity and the risk of cancer mortality. The risk of death from prostate cancer in obese men was 34% (Study I) and 36% (Study II) when compared to men of normal weight (Rodriguez et al, 2001; Calle et al, 2003). Furthermore, men over the age of 65 who engaged in vigorous exercise more than 3 hours per week had a 70% reduction in prostate cancer-specific death (Giovannucci et al, 2005). The body composition changes associated with ADT may portend a worse prognosis for men with prostate cancer. Regular vigorous exercise may help patients limit the accumulation of fat and even prevent prostate cancer progression.

Diabetes and Metabolic Syndrome

Given the changes in body habitus, it is not surprising that metabolic syndrome, a clustering of specific cardiovascular disease risk factors related to insulin resistance, is present in more than 50% of men undergoing long-term ADT (Braga-Basaria et al, 2006). Unlike classic metabolic syndrome characterized by visceral fat accumulation, however, ADT preferentially increased subcutaneous fat: furthermore, high-density lipoprotein (HDL) cholesterol concentrations were increased (Smith et al, 2008a). Short-term ADT affected serum lipid and hemoglobin A_{1c} independent of statin therapy (Yannucci et al, 2006). In a small, but carefully controlled prospective study, ADT significantly decreased insulin sensitivity in men with prostate cancer (Smith et al, 2006). These findings were supported by a larger observational study (73,196 men with prostate cancer) in which there was a significant risk of developing diabetes with ADT (Keating et al, 2006). In a subset analysis of a phase III trial of the selective estrogen receptor modulator toremifene for the prevention of osteoporosis in men undergoing ADT, placebo-treated patients had increases in low-density lipoprotein (LDL) cholesterol and triglycerides, which were significantly decreased with toremifene (Smith et al, 2008b).

Cardiovascular Morbidity and Mortality

Given the generally adverse effects of ADT on body habitus, glucose metabolism, and lipid profiles, it is not surprising that studies have found ADT is associated with increased cardiovascular morbidity and mortality. The effects appear to be most pronounced in men with lower-risk prostate cancer treated with ADT. In a large (22,816 subjects) population-based registry, newly diagnosed prostate cancer patients who received ADT for at least 1 year had a 20% higher risk of cardiovascular morbidity compared to similar men who did not receive ADT (Saigal et al, 2007). In men over the age of 65 undergoing radical prostatectomy who also received ADT, the

cumulative incidence of cardiovascular death was 5.5% over 5 years compared to 2.0% in those not receiving ADT (Tsai et al, 2007). On the other hand, in men with locally advanced prostate cancer treated with radiation therapy and ADT, there was not an increase in cardiovascular mortality compared to men receiving radiation therapy alone (Efsthathiou et al, 2008).

Gynecomastia

Depending on the agents used in ADT, alterations in breast tissue are common. Gynecomastia (an increase in breast tissue) and mastodynia (breast tenderness) may occur together or independently. Estrogenic compounds such as DES induce gynecomastia in 40% of patients (Smith, 1996). Likewise, the peripheral conversion of testosterone to estradiol associated with the antiandrogens induces gynecomastia at high rates: 66.3% of men taking 150 mg of bicalutamide developed gynecomastia and 72.7% developed mastodynia.

Prophylactic radiation therapy (10 Gy) has been used to prevent or reduce painful gynecomastia (Payne et al, 2002) as a result of DES or antiandrogen therapy. Radiation has no benefit once gynecomastia has begun. Liposuction and subcutaneous mastectomy have been used to treat established gynecomastia (Higano, 2003). The selective estrogen receptor modulator tamoxifen has been used to treat mastodynia (Serels and Melman, 1998).

Anemia

The anemia associated with ADT is normochromic, normocytic and is very common: 90% of men receiving combined androgen blockade experienced declines in hemoglobin concentration of at least 10% (Strum et al, 1997). Although anemia can be further complicated by tumor growth in the marrow space, compromising hematopoiesis, even men with nonmetastatic prostate cancer experience anemia with ADT (Choo et al, 2005). Unfortunately, anemia (defined as hemoglobin <12 g/dL) is associated with a shorter survival in those patients who were anemic prior to initiation of ADT (Beer et al, 2004b). Declines in hemoglobin begin within 1 month of ADT initiation (Strum et al, 1997) and continue for 24 months (Choo et al, 2005). Compensatory mechanisms limit the symptomatic effects of anemia to a small subset (13%) of men (Strum et al, 1997).

The anemia with ADT is thought to be secondary to lack of testosterone stimulation of erythroid precursors and a decrease in erythropoietin production. In an animal model, however, erythropoietin levels increased after ADT (Voegeli et al, 2005). Whatever the etiology, clinically, patients respond to recombinant human erythropoietin. The anemia is reversible after stopping ADT, but this may take up to a year (Strum et al, 1997).

COMBINATION THERAPY

The advent of nonsurgical, reversible hormone therapy coupled with its profound effects on prostate cancer have led to broad investigations of the combination of ADT with nearly every other treatment applied to prostate cancer. In some cases, most notably external beam radiotherapy, the combination clearly improves the outcomes; in others, most notably radical prostatectomy, there is no obvious benefit.

With Radical Prostatectomy

In nonrandomized clinical trials of ADT prior to radical prostatectomy, the effects on the final surgical specimen were dramatic. Positive surgical margin rates fell from nearly 50% in hormonal intact patients to 15% in ADT patients (Lee et al, 1997). Glands with no evidence of malignancy (P0) were not uncommon. There was a nonsignificant trend toward improved biochemical outcome with neoadjuvant ADT. Based on these findings and a perception that neoadjuvant ADT reduced blood loss and rendered the

TABLE 120-2 Randomized Prospective Studies of Neoadjuvant ADT before RRP: No Significant Difference in Biochemical (PSA) Progression

procedure easier to perform, three randomized prospective studies compared 3 months of ADT followed by radical retropubic prostatectomy (RRP) to RRP alone (Witjes et al, 1997; Soloway et al, 2002; Klotz et al, 2003) (Table 120-2). In both short (mean 15 months) and longer (4 to 7 years) follow-up, there was no significant difference in PSA progression between the groups. The lack of improved biochemical recurrence in these three randomized prospective trials using 3 months of neoadjuvant ADT before RRP argues strongly that this combination is not indicated in the treatment of prostate cancer.

With Radiation Therapy

Unlike the lack of long-term improved cancer-specific progression with the combination of ADT and radical prostatectomy, several phase III clinical trials have shown a benefit with the combination of ADT and external beam radiation in overall survival, cancer-specific survival, or freedom from disease progression. It should be noted that the benefit appears to be in men with locally advanced disease and/or those with high-grade, high-risk disease.

A phase III study comparing radiation alone to the combination of radiation and orchiectomy in men undergoing pelvic lymph node dissection was closed because of a high frequency of progression in the radiation-only arm (Granfors et al, 1998). A report based on this study at a median 9.3 years of follow-up demonstrated a significant difference in clinical progression (61% vs. 31%), overall mortality (61% vs. 38%), and prostate cancer-specific mortality (44% vs. 27%) in 91 men randomized to radiation alone versus radiation and orchiectomy, respectively (Granfors et al, 1998). These observations were supported by another study randomizing men with locally advanced prostate cancer to radiation alone versus radiation combined with goserelin for 3 years (Bolla et al, 1997). The significant disease-free and overall survival advantage of the combination was confirmed at a long-term analysis of the trial (Fig. 120-7) (Bolla et al, 2002). Clearly, in locally advanced, high-risk disease, the combination of radiation therapy with ADT is certainly better than radiation alone. A number of trials have been designed to address the timing of ADT (length, neoadjuvant, adjuvant) (Crook et al, 2004); some of the results are summarized in Table 120-3 and in several review articles (D’Amico, 2002; Lawton, 2003). Changes in the dose and field of the external beam radiation therapy make direct study-to-study comparisons difficult: unlike the uniformity of radical prostatectomy (complete ablation of the prostate), the optimum radiation technique remains undefined.

Figure 120-7. Kaplan-Meier estimates of overall survival by treatment group: 3 years of goserelin combined with external beam radiation versus external beam radiotherapy alone for locally advanced prostate cancer. CI, confidence interval. (From Bolla M, Collette L, Blank L, et al. Long-term results with immediate androgen suppression and external irradiation in patients with locally advanced prostate cancer (an EORTC study): a phase III randomised trial. *Lancet* 2002;360:103–8.)

Combined Androgen Blockade

Among all the efforts to improve the efficacy of ADT, none has been as widely studied as combinations of the various forms of hormone therapy, particularly if mechanistically nonredundant. For example, ablation of the source of androgen (castration) coupled with inhibition of LHRH with DES was one of the first combinations studied clinically to suggest improved survival (Nesbit and Baum, 1951); upon closer scrutiny in the first VACURG study, the survival advantage of this combination was lost (Blackard et al, 1973). Likewise, an early experience with an LHRH analogue and

*The 5-year overall survival and cancer-specific survival differences between the two study arms were not significant. At 10 years of follow-up, however, the combination of adjuvant goserelin and RT compared to RT alone was significantly different: for overall survival, 49% versus 39%, respectively; for cancer-specific survival, 84% versus 78%, respectively.

†Difference not significant.

‡Difference not significant.

§During 14 to 19 years of follow-up, 87% of RT-only arm and 76% of the RT + orchiectomy arm died (log rank $p = .03$); prostate cancer mortality was 57% and 35%, respectively (log rank $p = .02$).

¶Difference not significant.

ADT, androgen deprivation therapy; PSA, prostate-specific antigen; RT, radiation therapy.

an antiandrogen in 30 patients suggested improved outcomes compared to standard treatment (Labrie et al, 1983); upon extensive scrutiny in a meta-analysis of 27 prospective, randomized, international clinical trials of the combination of an antiandrogen with either castration or an LHRH agonist, the collective result was clinically insignificant (Prostate Cancer Trialists' Collaborative Group, 2000).

The concept of adding an antiandrogen to surgical castration or an LHRH agonist is based on the idea that, after the elimination of testicular androgens through surgical or medical castration, adrenal androgens still contribute to prostate cancer progression (Labrie et al, 1988; Miyamoto et al, 1998; Miyamoto and Chang, 2000). The fact that serum testosterone does not drop to zero following surgical or medical castration is clear evidence for additional sources of androgen (Geller, 1985; Sandow et al, 1988). The idea of trying to eliminate all sources of endogenous androgen in treating prostate cancer is not new: bilateral surgical adrenalectomy was performed with failure far outweighing success (Huggins and Scott, 1945). Eliminating all sources of endogenous androgen is also referred to, somewhat presumptuously, as "total androgen blockade" or "maximum androgen blockade"—as if such a state is actually achieved; the term *combined androgen blockade* (CAB) is more appropriate. The antiandrogens are nonspecific in blocking the binding of androgens to the AR: both testicular and adrenal androgens are affected. In concept, the approach is sensible and some clinical trials showed prolonged survival in patients with advanced prostate cancer treated with CAB compared to standard ADT (Crawford et al, 1989; Dijkman et al, 1997; Denis et al, 1998).

One study showing a survival advantage to CAB compared the antiandrogen flutamide (250 mg three times per day) in combina-

tion with *daily* leuprolide—a formulation not currently used—to placebo plus daily leuprolide in men with metastatic prostate cancer (Crawford et al, 1989). The combination therapy resulted in a significantly longer progression-free survival and longer overall median survival (35.6 vs. 28.3 months) when compared to the placebo-treated controls. In a hypothesis-generating subset analysis, the authors found that those patients with minimal metastatic disease (defined as the absence of metastases in the skull, ribs, long bones, and non-nodal soft tissue) enjoyed the largest survival benefit compared to similarly defined men receiving placebo. Another positive study compared orchiectomy plus the antiandrogen nilutamide to orchiectomy plus placebo (Dijkman et al, 1997): at 8.5 years of follow-up, the CAB group had significantly longer median time to progression (21.2 vs. 14.7 months) and higher overall survival (37 vs. 29.8 months). Finally, a study in which depot goserelin combined with flutamide was compared to orchiectomy showed increased survival in the CAB group (Denis et al, 1998).

Against the backdrop of these positive studies are a host of randomized trials showing no significant survival advantage for CAB. A landmark randomized clinical trial comparing surgical castration alone to surgical castration combined with flutamide in men with metastatic prostate cancer showed no significant survival advantage for those undergoing CAB (Eisenberger et al, 1998). Unlike the previous study suggesting an advantage of CAB in men with minimal metastatic disease (Crawford et al, 1989), stratifying outcome by disease burden—defined prospectively—was not significant.

In a clinical trial, when the variability in a possible outcome is large and the effect being studied may be small, confidence in the

interpretation of the result is dependent on the size of the study. When several studies testing the same idea in presumably the same patient population demonstrate both positive and negative results, concerns about the existence of a real treatment effect increase. Such is the case with many of the studies of CAB: because they consist of only a few hundred men or are based on subset analysis of a larger study, there is a risk that chance and not an antiandrogen drives the survival outcomes. Those favoring a role of CAB in prostate cancer management point to the selected studies supporting their point of view, only to be met by those against CAB who trot out the negative studies that support their point of view.

Fortunately, the idea of CAB has been very extensively studied: since the early 1980s, 27 randomized studies including 8275 men have been conducted, providing the basis for a meta-analysis comparing CAB to standard ADT (Prostate Cancer Trialists' Collaborative Group, 2000). In these 27 studies, 88% of patients had metastatic disease; the remainder had locally advanced disease. Interestingly, in studies recording specific cause of death, 20% died from causes other than prostate cancer: not everyone with metastatic prostate cancer dies from the disease. In the meta-analysis, the 5-year survival with CAB was 25.4% compared to 23.6% with standard ADT, a nonsignificant gain in favor of CAB of 1.8% (Fig. 120-8). Studies including the steroidal antiandrogen cyproterone acetate had a slightly worse outcome on the CAB arms (5-year survival 15.4% vs. 18.1% for ADT alone), suggesting increased non-prostate cancer deaths in those receiving cyproterone acetate. When studies examining the outcomes of the non-steroidal antiandrogens flutamide or nilutamide were considered independent of those with cyproterone acetate, the 5-year survival improved from 24.7% (standard ADT) to 27.6% for CAB. This 2.9% improvement was significant, but the meta-analysis had a 0% to 5% range of uncertainty about the true size of the benefit.

Figure 120-8. Meta-analysis of maximal androgen blockade versus testicular androgen suppression alone in 27 randomized trials and 8275 patients, with an average follow-up of about 5 years. Overall survival curves are for all men irrespective of the antiandrogen used. (From Prostate Cancer Trialists' Collaborative Group. Maximum androgen blockade in advanced prostate cancer: an overview of randomised trials. *Lancet* 2000;355:1491-8.)

TIMING OF THERAPY

The timing of the initiation of ADT, although not as extensively studied as CAB, remains one of the most contested areas of prostate cancer management. The spectrum of opinions ranges from primary ADT at time of diagnosis to the initiation of ADT at the first sign of primary prostate cancer failure (early) to initiation of ADT only with objective evidence of distant metastatic disease (late) (Reese, 2000; Walsh et al, 2001; Loblaw et al, 2004; Miyamoto et al, 2004; Sharifi et al, 2005). Unfortunately, the clinical data to support the various perspectives are limited and it is not uncommon for proponents of a particular opinion to extrapolate data from one clinical state to another for which data do not exist. **There is no question that early ADT delays biochemical and clinical disease progression, but the effects of early ADT on survival remain unclear (Ryan and Small, 2005).** Likewise, there is no question that ADT is indicated in symptomatic, metastatic disease. For the sake of this discussion, ADT will be considered continuous, from initiation until death; intermittent ADT is discussed in a subsequent section. Likewise, this discussion focuses on overall and prostate cancer-specific survival resulting from ADT.

Continuous Androgen Deprivation Therapy: Immediate versus Delayed

It is useful to consider some facts about ADT and prostate cancer progression. First, the natural history of prostate cancer progression, even in the hormonally intact individual, is protracted. In a cohort of 304 men with a biochemical recurrence after radical prostatectomy, the median time from recurrence to metastasis was 8 years and from metastasis to death was 5 years (Pound et al, 1999). In updates of this study, the median time to prostate cancer-specific mortality had, initially, not been reached after 16 years of follow-up but was subsequently found to be 168 months (14 years) (Freedland et al, 2005; Makarov et al, 2008). Therefore, even in the absence of ADT, men with progressive prostate cancer live for a long time. Second, despite dramatic clinical responses, men undergoing ADT either will die of a non-prostate cancer cause (estimated at 20% based on the CAB meta-analysis) or will eventually demonstrate evidence of castration-resistant disease and die of prostate cancer. In a randomized prospective study of orchiectomy with or without the antiandrogen flutamide, only 7% of men were still alive at 10 years after the initiation of ADT (Tangen et al, 2003). In a study using a 5% national random sample of Medicare beneficiaries undergoing ADT for prostate cancer, the median overall survival after the initiation of ADT was 4.4 years, and after 8 years only 4.5% of the population was still alive (Krupski et al, 2004). Third, ADT is not an innocuous therapy: beyond the quality-of-life side effects discussed earlier, in a global sense men on ADT age more rapidly; the natural extension of more rapid aging is earlier death. Therefore the long natural history of prostate cancer progression coupled with the inevitability of its progression after ADT initiation in a population with a growing risk of death from all causes should temper enthusiasm to indiscriminately apply this therapy to all men with progressive prostate cancer.

The questions about the timing of ADT are not new. In 1973, the results of a large (more than 1900 men) study performed in the Veterans Administration of early versus late hormonal therapy were reported (Byar, 1973). In men with metastatic disease, death from prostate cancer occurred in 48% of those treated early versus 47% of those treated late. In men with locally advanced disease, death from prostate cancer occurred in 14% of those treated early versus 17% of those treated late. The lack of a survival benefit in men treated early coupled with the known side effects of therapy support the recommendation that hormonal therapy should be instituted in men with symptomatic disease. Since that time, several randomized studies have applied ADT at different times in the natural history of prostate cancer; the results of those studies must be considered within the context of when ADT is used and the circumstances of the study.

Results in Clinically Localized Disease

In the bicalutamide Early Prostate Cancer program, men were randomized to bicalutamide 150 mg or placebo in addition to standard care (See et al, 2003). End points of these trials included overall survival, progression-free survival, and tolerability. In the subset of men with clinically localized disease, the overall survival was significantly worse in those undergoing ADT with bicalutamide 150 mg compared to placebo (Iversen, 2004; Iversen et al, 2004). No specific cause for this decline in overall survival with ADT was identified, but it appeared to be the result of increased deaths from non-prostate cancer causes for those on bicalutamide.

In a community-based cohort study (Prostate Cancer Outcomes Study), men with localized prostate cancer treated with primary ADT within 1 year of diagnosis had a 91% cancer-specific survival but only a 66% overall survival at 5 years (Graff et al, 2007). A larger study of 19,271 men 66 years or older with localized prostate cancer who did not receive definitive local therapy found that primary ADT was associated with lower 10-year prostate cancer-specific survival compared to those on conservative management (Lu-Yao et al, 2008). Although this finding could be the result of more aggressive prostate cancers requiring immediate primary ADT, there was no increase in 10-year overall survival with primary ADT. The authors concluded that “primary ADT is not associated with improved survival in the majority of elderly men with localized prostate cancer when compared with conservative management” (Lu-Yao et al, 2008). Finally, in a retrospective, matched cohort study of patients who received adjuvant ADT (within 90 days of node-negative, radical prostatectomy) compared to those who did not, there was a 3% improved prostate cancer-specific survival (98% vs. 95%, respectively, $P = 0.009$) but no improvement in overall survival (83% in both groups) (Siddiqui et al, 2008).

Primary ADT—defined as the administration of ADT to men without metastases as sole therapy at the time of diagnosis—has been widespread particularly in men over 65 years old: in one study, up to 40% of these men received primary ADT (Shahinian et al, 2006). A retrospective cohort study from three integrated health care plans found that primary ADT was associated with neither a risk of all-cause mortality nor a risk of prostate cancer-specific mortality (Potosky et al, 2014). Primary ADT was associated with decreased risk of all-cause mortality only in men with high risk of prostate cancer progression. It therefore appears that primary ADT does not provide a survival benefit for most men with clinically localized prostate cancer.

These observations are important for several reasons. First, they resoundingly answer the claim that “ADT can’t hurt, so why not use it early?” In the Early Prostate Cancer study, men without ADT had significantly better survival. Second, when ADT is applied in situations in which the risk of death from prostate cancer is already low, demonstration of a prostate cancer-specific survival benefit from that therapy will be very difficult. If ADT itself increases overall mortality compared to no ADT, then demonstration of a prostate cancer-specific benefit will be nearly impossible. Third, men with localized, low-risk prostate cancer should not be treated with ADT without first being informed of these findings. Avoidance of prostate cancer progression and death may come at the expense of unnecessary side effects or a higher overall death rate. These data support the hypothesis that the more rapid aging associated with ADT will bring men with low-risk prostate cancer more quickly to their deaths.

Results in Lymph Node Metastatic Prostate Cancer

A randomized prospective study of immediate ADT compared to delayed ADT was performed by the Eastern Cooperative Oncology Group (ECOG) in men with histologic evidence of metastatic prostate cancer in regional lymph nodes after radical prostatectomy. At the time of the initial report, at 7.1 years of median follow-up, overall survival significantly ($P < .02$) favored the immediate ADT group compared to the delayed ADT group: in the immediate ADT group, only 3 of the 7 deaths were due to prostate cancer

Figure 120-9. Long-term overall survival of men randomized to immediate hormone therapy compared to observation after radical prostatectomy with pelvic lymphadenectomy in men with node-positive prostate cancer. At median 11.9-year follow-up, overall survival in the immediate hormone therapy group was 64% (30/47) compared to 45% (23/51) in the observation group ($P = .04$, log rank). (From Messing EM, Manola J, Yao J, et al; Eastern Cooperative Oncology Group study EST 3886. Immediate versus deferred androgen deprivation treatment in patients with node-positive prostate cancer after radical prostatectomy and pelvic lymphadenectomy. *Lancet Oncol* 2006;7:472-9.)

compared to 16 of the 18 cancer-specific deaths in the delayed ADT group (Messing et al, 1999). In an updated report, median overall survival was significantly longer in the immediate ADT compared to the delayed ADT group: 13.9 versus 11.3 years, respectively (Fig. 120-9) (Messing et al, 2003, 2004). Eight of 18 men in the immediate ADT group died of prostate cancer compared to 25 of 28 men in the delayed ADT group. Given the previous discussion of the increased non-prostate cancer death rate with bicalutamide 150 mg, it is interesting that there have been proportionally more non-prostate cancer deaths in the immediate ADT group (55%) compared to the delayed group (11%). Nevertheless, based on this randomized, prospective trial, there appears to be a benefit to immediately ADT in those men with histologic evidence of lymph node metastases at the time of radical prostatectomy.

There have been several criticisms of this study (Eisenberger and Walsh, 1999). First, the study was designed to enroll 240 patients, yet only enrolled 100. When a large difference in outcome is found in a small study, there is a risk of a type I error (assuming a treatment has an effect when in reality it does not). There was no evidence for an imbalanced randomization, but unrecognized prognostic factors can influence outcomes in smaller studies. Second, Gleason grading was not centralized and the absence of a correlation between histologic grade and survival suggests an imbalance may exist. This concern was partially addressed by a central pathologic review in a blinded fashion of a subset (51%) of the initial specimens. Based on this reanalysis, there was no significant difference in outcomes by treatment arm. Third, those on delayed ADT experienced disease progression and death from prostate cancer that was much more rapid than would have been expected from contemporary series of node-positive patients (deKernion et al, 1990; Zincke et al, 1992; Cadeddu et al, 1997). In contrast to the ECOG study, an observational study of 731 men with node-positive prostate cancer after radical prostatectomy between 1991 and 1999 found no significant difference in overall survival in those who received adjuvant ADT (within 120 days of surgery, $n = 209$) compared to those who did not (Wong et al, 2008).

The magnitude of the difference observed in the ECOG study has not been seen in larger similar—but not identical—patient populations. In a European Organisation for the Research and Treatment of Cancer trial of immediate versus delayed ADT in pN1-3M0 patients without local treatment of the primary tumor, 302 men were randomized to delayed ADT (n = 115) or immediate ADT (n = 119) (Schröder et al, 2004). At a median follow-up of 13 years, the median overall survival in the immediate ADT group was 7.6 years (95% CI 6.3 to 8.3 years) versus 6.1 years (95% CI 5.7 to 7.3 years) in the delayed ADT group. The 10-year cumulative incidence of death from prostate cancer was 55.6% in the delayed ADT group versus 52.1% in the immediate ADT group (Schröder et al, 2009) (Fig. 120-10). Based on these data, 20.8 patients would need to be treated with immediate ADT to spare one life at 5 years and 28.6 to spare one life at 10 years.

Results in Locally Advanced, Asymptomatic Metastatic Disease or Disease Not Suitable to Local Treatment

A trial of immediate versus delayed ADT in men with locally advanced or asymptomatic prostate cancer was conducted by the Medical Research Council (MRC) Prostate Cancer Working Party Investigators Group (1997). A total of 934 men were included (500 M0, 261 M1, and 173 Mx), with 469 randomized to immediate ADT and 465 randomized to delayed ADT. As originally reported, there was a significant survival advantage in the M0 group; on longer follow-up the overall survival advantage is not significant (Kirk, 2004). Overall, men in the delayed ADT arm died significantly more often from prostate cancer and had significantly more symptoms related to disease progression. Based on these data, the benefits of immediate ADT would seem to support its use.

There have been many criticisms of the MRC trial. First, 6% (29/465) of men in the delayed ADT arm “died from prostate cancer before treatment could be started,” meaning they died without ever

receiving ADT. Delayed ADT is not the same as no ADT. Second, 173 of the subjects included in the study were not staged (Mx). When nearly 1 in 5 men could have been incorrectly randomized, the impact on the study’s outcome could be significant. Third, almost 10% of men in the delayed group were treated only when they had developed spinal cord compression or pathologic fractures. The emergency implementation of hormonal therapy is a rare event in patients followed closely; it certainly should not occur in 10% of patients. Finally, the lack of a standardized follow-up protocol—follow-up and management were otherwise according to the participating clinician’s normal practice—may provide meaningful “real-world” results but likely introduces major deviations from rigorous clinical trial design.

Since the majority of men in the MRC study have died (92.5% in the immediate ADT group, 93.6% in the delayed ADT group), the data are now mature and unlikely to change significantly in the future (Kirk, 2004). Time to death from prostate cancer remains significantly in favor of the immediate ADT group ($P = .019$), whereas time to death from any cause is not significantly different between the groups ($P = .0914$). The total difference in prostate cancer-specific deaths was 46 men: 241 died from prostate cancer in the immediate ADT arm, 287 in the delayed ADT arm (Kirk, 2004); the impact of the 29 men in the delayed ADT who never received ADT on this result is unknown, but could reasonably be considered significant. Unlike the increased overall mortality for immediate ADT found in the Early Prostate Cancer bicalutamide 150 mg study for localized, low-risk disease, no similar increase was observed in immediate ADT in the MRC study of a higher-risk cohort.

Immediate versus delayed ADT was studied in another group (n = 985) of men not suitable for local treatment (refused local treatment; had decreased life expectancy, advanced local tumor stage, and/or severe comorbidities) (Studer et al, 2006, 2014). Unlike the MRC study, immediate ADT resulted in a significant, albeit small, improvement in overall survival but no difference in

Figure 120-10. Overall mortality, cancer-related mortality, and non-cancer-related mortality with early versus delayed androgen deprivation therapy in men with T2-T3pN1-3M0 prostate cancer without local treatment of the primary tumor. (From Schröder FH, Kurth KH, Fossa SD, et al. Early versus delayed endocrine treatment of T2-T3 pN1-3 M0 prostate cancer without local treatment of the primary tumour: final results of European Organisation for the Research and Treatment of Cancer protocol 30846 after 13 years of follow-up [a randomised controlled trial]. Eur Urol 2009;55:14-22.)

Figure 120-11. Prostate cancer (PCa), non-PCa, and overall mortality with deferred androgen deprivation therapy (ADT) versus continuous ADT. (From Studer UE, Whelan P, Wimpissinger F, et al; EORTC Genitourinary Cancer Group. Differences in time to disease progression do not predict for cancer-specific survival in patients receiving immediate or deferred androgen-deprivation therapy for prostate cancer: final results of EORTC randomized trial 30891 with 12 years of follow-up. *Eur Urol* 2014;66:829–38.)

prostate cancer–specific mortality or overall symptom-free survival (Fig. 120-11). Interestingly, in the delayed ADT arm, 30.8% died without ever needing treatment.

Immediate versus Delayed Androgen Deprivation Therapy: Integrating the Data

With the emerging data from ongoing clinical trials and the recently published results of new studies, it is possible to consider the timing of ADT from the perspective of the natural history of the disease.

1. There is no survival benefit to immediate ADT in low-risk, localized prostate cancer. In fact, from the perspective of overall survival, men treated in this fashion do significantly worse than those spared ADT in this setting.
2. In locally advanced, asymptomatic metastatic and clinically present but undefined prostate cancer treated in a community setting with limited disease monitoring, immediate ADT results in significantly better prostate cancer–specific survival but not better overall survival. On the other hand, in men deemed not suitable for local treatment, immediate ADT improved overall survival but not prostate cancer–specific survival.
3. In node-positive disease without primary treatment, there is no significant advantage to immediate ADT, although on balance there is a 1.5-year median survival advantage. In node-positive disease with radical prostatectomy, there is a significant survival advantage favoring immediate ADT, with a 2.6-year difference in median overall survival.

Intermittent versus Continuous Androgen Deprivation Therapy

The use of intermittent ADT has been studied in at least seven large randomized phase III clinical trials (Boccon-Gibod et al, 2007). The rationale for intermittent ADT is based on two complementary ideas. First, in preclinical animal models (Shionogi breast cancer

tumor, LNCaP prostate cancer tumor) exposure to androgen deprivation on an intermittent—rather than continuous—basis lengthened the time to the emergence of androgen-refractory cancer growth (Akakura et al, 1993; Sato et al, 1996). Since castration-resistant prostate cancer is synonymous with lethal prostate cancer, any manipulation of the hormonal milieu that can delay progression into this state would be welcomed. Second, many patients (and their physicians) have increasingly questioned the real benefit of continuous ADT, given the profound and often debilitating side effects associated with its use. With readily reversible ADT, recovery of normal testosterone levels should occur when androgen ablation is stopped. In theory, the quality-of-life side effects of ADT on intermittent treatment should be some fraction of those side effects when ADT is used continuously.

Intermittent ADT was studied in a group of men with a rising PSA after primary or salvage radiotherapy (Crook et al, 2012). Specifically, men were randomized to receive intermittent or continuous androgen deprivation with a primary end point of overall survival. Intermittent treatment was provided in 8-month cycles, with nontreatment periods based on PSA levels. At a median follow-up of 6.9 years, there were 268 deaths in the intermittent therapy group and 256 deaths in the continuous therapy group: median overall survival was 8.8 years in the intermittent group versus 9.1 years in the continuous group (Fig. 120-12). Based on a noninferiority trial design, intermittent therapy was not inferior to continuous therapy for overall survival. Disease-specific death (prostate cancer and related treatments) was more common in the intermittent therapy arm compared to the continuous therapy arm (120 versus 94, respectively). Conversely, deaths unrelated to prostate cancer were more common in the continuous therapy arm compared to the intermittent therapy arm (162 versus 148, respectively).

Attrition from intermittent androgen deprivation progressively increased over time as patients either developed castration-resistant prostate cancer or died of another cause. Attrition only occurred in 5% of men in the first interval, whereas 68% had stopped intermittent therapy by the third interval. On the other hand, duration of intermittent ADT progressively shortened over

Figure 120-12. Overall survival in patients undergoing intermittent androgen deprivation therapy (IAD) compared to those undergoing continuous androgen deprivation therapy (CAD) in a cohort of men previously treated with primary or salvage radiation therapy. (From Crook JM, O’Callaghan CJ, Duncan G, et al. Intermittent androgen suppression for rising PSA level after radiotherapy. *N Engl J Med* 2012;367:895–903.)

time: the median nontreatment interval between cycles was 20.1 months for the first treatment cycle, 13.2 months for the second cycle, 9.1 months for the third, and 4 to 5 months thereafter. A secondary end point, improved quality of life in the intermittent therapy arm, was associated with significantly better scores for hot flashes, desire for sexual activity, and urinary symptoms. For the functional domains of physical, role, and global health the intermittent therapy arm was slightly better, but the differences were not significant. Overall, concerning quality of life the authors concluded that “the difference is not as profound as one might expect” (Crook et al, 2012).

Noninferiority trials require fewer subjects than for an equivalence trial, making them easier to accrue and complete. It is important to recognize that noninferiority is not the same as equivalence; trial design is based on a definition of noninferiority if a prespecified upper margin of a hazard ratio is not exceeded. In this trial, the upper limit was 1.25, meaning up to 25% more men on the intermittent arm could die of any cause and intermittent treatment would still be considered noninferior. In this trial, the upper limit of the 95% CI was 1.22, which is below 1.25 and therefore met the prespecified definition.

Intermittent ADT was studied in a group of men with newly diagnosed metastatic prostate cancer (Hussain et al, 2013). After a 7-month induction of ADT in all patients, men whose PSA level had declined to 4 ng/mL or lower (indicating androgen sensitivity) were randomized to receive intermittent or continuous androgen deprivation with coprimary end points of overall survival and quality of life at 3 months after randomization. At a median follow-up of 9.8 years, median overall survival was 5.8 years in the continuous arm and 5.1 years in the intermittent arm (hazard ratio for death with intermittent therapy, 1.10; 90% CI 0.99 to 1.23) (Fig. 120-13). Unfortunately, these findings are statistically inconclusive: the CI for survival exceeded the upper boundary for noninferiority (1.20), meaning one cannot conclude that intermittent therapy was noninferior to continuous therapy. Furthermore, because the lower limit of the CI (0.99) did not exclude 1.00, one cannot conclude that intermittent therapy was significantly inferior to continuous therapy. A reasonable clinical interpretation of this statistically inconclusive study is that intermittent therapy is not superior to continuous therapy in men presenting with metastatic prostate cancer, and may be worse. In the words of the authors “given that nearly the entire confidence interval tends to

Figure 120-13. Overall survival in patients undergoing intermittent androgen deprivation therapy compared to those undergoing continuous androgen deprivation therapy in a cohort of men with newly diagnosed metastatic, hormone-sensitive prostate cancer. (From Hussain M, Tangen CM, Berry DL, et al. Intermittent versus continuous androgen deprivation in prostate cancer. *N Engl J Med* 2013;368:1314–25.)

favor continuous therapy, the results suggest that intermittent therapy may compromise survival” (Hussain et al, 2013). Quality-of-life scores were significantly better in the intermittent arm (less likely to report impotence, better mental health) at 3 months. At 9 and 15 months, the quality-of-life scores favored intermittent therapy but the differences were not significant.

The treatment schedules for intermittent androgen deprivation vary slightly between the rising PSA after radiation therapy trial (Crook et al, 2012) and the metastatic disease trial (Hussain et al, 2013): both used an induction period of ADT (8 months and 7 months, respectively). If the PSA was less than 4 ng/mL, both trials stopped ADT. Androgen deprivation was restarted if the PSA reached 10 or 20 ng/mL, respectively, or for clinical symptoms. In the metastatic disease trial, ADT could also be restarted when the PSA reached baseline. The development of castration-resistant prostate cancer required that the patient be on ADT and demonstrate clinical progression or PSA increases monthly for 3 months. In both trials castration-resistant prostate cancer was managed with continuous ADT. The treatment schedules provide some guidance in managing patients on intermittent ADT, but there is no consensus on the ideal schedule.

ECONOMIC CONSIDERATIONS

In the United States, the cost of drug therapy for ADT (LHRH agonists) in the Medicare program was \$761,000,000 in 1997 and rose to \$1.2 billion in 2003 (Holtgrewe et al, 2000; Shahinian et al, 2006). Indeed, in 2003, LHRH agonists were the second highest Medicare Part B expenditure. This expense is not unique to the United States: in 1997, the annual cost of these agents in Sweden was \$17,000,000 and in Germany the annual cost was \$142,000,000. In a study of 96 men undergoing ADT for prostate cancer over a 10-year period, the cost of LHRH agonists ranged from greater than 10.7 to 13.5 times the cost of bilateral orchiectomy and the cost of CAB was 17.3 to 20.9 times greater (Mariani et al, 2001). Clearly, the cost of ADT, as currently being delivered, is extraordinary.

Although DES is associated with increased cardiovascular toxicity, from a strictly cost point of view, it is the cheapest form of ADT, particularly at the 1-mg/day dose, with no prophylactic breast irradiation (Mariani et al, 2001). There is no significant survival advantage of LHRH agonists over orchiectomy so, from an economic perspective, LHRH agonists would only be more cost effective than orchiectomy if a patient only lived for a few months

KEY POINTS

- Androgen deprivation is one of the most effective therapies against any solid tumor; unfortunately, with time almost all prostate cancers will become androgen refractory.
- All current forms of androgen deprivation therapy (ADT) function by either lowering levels of circulating androgens or blocking the binding of androgen to the androgen receptor.
- Almost all castration-resistant prostate cancer remains sensitive to androgen; therefore ADT should continue in castration-resistant disease.
- Relative to testosterone and dihydrotestosterone, the adrenal androgens are weak.
- There are four general forms of ADT: (1) ablation of androgen sources, (2) antiandrogens, (3) inhibition of LHRH and/or LH, and (4) inhibition of androgen synthesis.
- Bilateral orchiectomy reduces testosterone by 90% within 24 hours of surgery.
- Nonsteroidal antiandrogens cause LH and testosterone levels to increase.
- Serious liver toxicity is a possible side effect of all antiandrogens.
- Antiandrogens can act as agonists on some tumors; antiandrogen withdrawal results in PSA declines in 15% to 30% of patients.
- Bicalutamide 150 mg monotherapy appears to have equivalent efficacy to medical or surgical castration for locally advanced or metastatic prostate cancer.
- Enzalutamide improves overall survival in metastatic, castration-resistant prostate cancer after treatment with chemotherapy.
- Abiraterone improves overall survival in metastatic, castration-resistant prostate cancer both before and after treatment with chemotherapy.
- All LHRH agonists induce a testosterone increase upon initial exposure. Coadministration of an antiandrogen functionally blocks the effects of testosterone.
- The magnitude and rapidity of the initial response to ADT are strong predictors of the durability of that response.
- The side effects of ADT include osteoporosis, hot flashes, sexual dysfunction, cognitive function alterations, changes in body habitus, gynecomastia, and anemia. These side effects can be progressive but are responsive to other treatments.
- There is no evidence that 3 months of neoadjuvant ADT prior to radical prostatectomy improves biochemical outcomes.
- There is considerable evidence that ADT combined with external beam radiation therapy improves overall survival, cancer-specific survival, and freedom from disease progression. The optimal timing and duration of ADT in this combination remains undefined.
- Based on a large meta-analysis of many clinical trials, combined androgen blockade with nonsteroidal antiandrogens provides about a 3% survival benefit at 5 years compared to standard ADT.
- The natural history of prostate cancer progression is protracted. Many men with evidence of disease will never require ADT.
- The use of ADT in low-risk, localized prostate cancer increases overall (non-prostate cancer) mortality.
- In lymph node metastatic prostate cancer, ADT improves overall survival if the primary tumor is removed but has no significant effect if the primary tumor is not removed.

after initiation of ADT. The 3-month formulations of leuprolide acetate and goserelin become more expensive than orchiectomy upon the administration of a second 3-month depot; specifically, the break-even point for leuprolide acetate is 4.2 months and goserelin is 5.3 months compared to orchiectomy (Mariani et al, 2001).

CAB is the most expensive form of ADT. Although there is no significant benefit of CAB over orchiectomy alone (Eisenberger et al, 1998), some patients may experience a large benefit. Assuming a cost-effectiveness threshold of \$100,000—meaning the expense of CAB minus the expense of orchiectomy—for each quality-adjusted life year, CAB would need to decrease the risk of disease progression by 20% compared to orchiectomy to be considered cost effective (Aronson et al, 1999). The earlier medical ADT is initiated, the more expensive it becomes: in models examining the cost effectiveness, ADT was most cost effective if initiated after patients became symptomatic from prostate cancer metastases (Bayoumi et al, 2000). In this model, LHRH agonists, nonsteroidal antiandrogens, and CAB had higher costs and lower quality-adjusted survival than orchiectomy.

If orchiectomy is just as effective and so much cheaper, why isn't it more widely used? In two studies that offered orchiectomy versus medical therapy for ADT, 70% of patients chose medical therapy (Iversen et al, 1998). Clearly, patients (and physicians) choose medical ADT for reasons other than efficacy or expense. Indeed, the use of ADT in all stages of prostate cancer has increased significantly between 1989 and 2001: for example, primary ADT rose from 32.8% to 48.2% in men with high-risk disease (Cooperberg et al, 2003). Avoiding the largely psychological quality-of-life issues unique to orchiectomy (disfigurement, permanence), ADT comes at an expense that would seem disproportionate to the risk, and yet society has chosen to accept the expense.

Perhaps most sobering about the costs of ADT is the significant variability with which ADT is used by urologists. In a study of 61,717 American men with incident prostate cancer from 1992 until

1999, the total variance in the use of ADT attributable to the urologist was approximately 21%, which was significantly more than that attributable to tumor characteristics (approximately 9%) or patient characteristics (approximately 4%). In other words, "the urologist who sees a patient may be a more important determinant of whether that patient will receive androgen deprivation therapy than the characteristics of the tumor (e.g., stage or grade) or the patient (e.g., age and comorbidity)" (Shahinian et al, 2006). The challenge for urologists is to offer this expensive form of treatment to those patients who need it and to avoid ADT in those who do not (Schellhammer, 2006).

Targeted Treatments

Palliative Management

The Neuroendocrine/Anaplastic Phenotype

Conclusions

During the past several decades, endocrine manipulations that were developed to inhibit hormone-sensitive prostate cancer growth and differentiation have constituted the basic strategy for the systemic control of prostate cancer. Suppression of gonadal testosterone is the central principle of androgen deprivation therapy (ADT), and this represents one of the most effective systemic treatments known for solid tumors. Although the therapy is extremely effective initially, virtually all patients eventually develop biochemical and clinical evidence of treatment resistance. The outcomes with conventional endocrine therapy have changed significantly but only modestly during the past few decades. Progression-free and overall survival figures of patients with metastatic disease with various methods of ADT have ranged from 12 to 20 months and 24 to 36 months, respectively (Leuprolide Study Group, 1984; Crawford et al, 1989; Denis et al, 1993; Eisenberger et al, 1998). Whereas somewhat longer survival times are reported in the more recent studies, this is most likely because of a “lead time” effect observed in contemporary populations of patients. The development of ADT resistance (i.e., cancer progression despite castrate levels of serum testosterone) is a virtually universal state that affects all patients treated with ADT. Undoubtedly, further improvement in the outcome of patients with metastatic castration-resistant prostate cancer (mCRPC) rests on the use of nonhormonal approaches that can effectively control the growth of the disease. However, recent understandings of the biology of castration-resistant prostate cancer (CRPC) have also led to the development of next-generation androgen receptor (AR)–targeting therapies, and some of these have also led to substantial clinical benefits.

During recent years, clinical investigations testing nonhormonal approaches have shown that systemic chemotherapy improves survival and quality of life in patients with castration-resistant disease. Advances in the understanding of the biology of prostate cancer and the characterization of key molecular pathways have added an important new dimension for treatment and the opportunity to design disease-specific targeted treatment approaches. Evolving data suggest that targeted approaches may play an important role in the treatment of prostate cancer that may improve the outcome in patients.

Progress in cell and molecular biology during the past decade has also enhanced our understanding of the mechanisms involved in the progression of prostate cancer, and this may provide the opportunity for rational planning of the appropriate timing of systemic therapeutic intervention with the objective of preventing or delaying progression of disease to lethal proportions. Cancer cells demonstrating the castration-resistant phenotype can be identified during the early stages of development of prostate cancer. Somatic

alterations of the AR are frequently observed in patients with evidence of disease progression after androgen deprivation. It has also been demonstrated that during cancer progression, in the absence of androgens, a molecularly altered AR can still undergo ligand-dependent activation by other hormones such as estrogens and progestational agents, as well as non-ligand-dependent activation by growth factors and cytokines (Feldman and Feldman, 2001; Gelmann, 2002; Nelson et al, 2003). The observation that the AR can still be activated even after long-term gonadal ablation suggests that it continues to play an important role in prostate cancer growth and might indeed be a reasonable target for treatment in patients with castration-resistant disease, as exemplified by the success with abiraterone and enzalutamide.

In the presence of androgens, prostatic cancer growth is based on a cell proliferation rate that exceeds that of cell death (Isaacs et al, 1992). Androgen ablation primarily affects the cell death rate by inducing a swift apoptotic cascade. As the tumor progresses, the threshold of apoptosis progressively rises to a point at which cell proliferation exceeds cell death (Berges et al, 1995). This results in the accumulation of endocrine-independent cells that eventually dominate the biologic behavior of prostate cancer in late stages.

Preclinical data suggest that the relatively low growth fraction expressed by prostate cancer cells (compared with other common adenocarcinomas) may be a determining factor to explain the relative insensitivity to conventional cytotoxic chemotherapy. The proliferation rate of prostate cancer cells, which is directly proportional to the growth fraction, appears to increase with tumor progression especially after androgen ablation. Cell proliferation antigens, such as Ki-67 expressed by cycling cells, may have important prognostic and therapeutic implications, because most of the conventional cytotoxic chemotherapeutic agents available are usually more effective in tumors with high proliferative rates such as lymphomas, small cell lung carcinomas, and germ cell tumors.

Changes in differentiation pathways in prostate cancer have been increasingly emphasized, particularly in the form of neuroendocrine/anaplastic cells (diSant’Agnese, 1995). Evolving experience suggests that this aggressive clinical entity may be responsive to treatment regimens frequently used for comparable tumors at other sites with similar phenotypic characteristics, such as small cell carcinoma of the lung. There is strong evidence to support the relationship between prostate cancer growth and various peptide growth factors (Djakiew et al, 1991; Steiner, 1993; Hofer et al, 1995; Kaplan et al, 1999; Nelson et al, 2003). Peptide growth factors may also exert their effects through the activation of the AR. Androgens are capable of inducing stromal production of various growth factors that could replace the androgen requirements for cell growth and

differentiation (Lee, 1996). In addition, cytokines released primarily by stromal cells, such as interleukin-6, may also be important in the pathogenesis of prostate cancer. Indeed, small molecule inhibitors and other modalities of treatment (e.g., monoclonal antibodies) are being actively designed to target intracellular pathways associated with the expression of various growth factors and their receptors. Such strategies have involved inhibition of receptor tyrosine kinase activity and other intracellular molecular pathways of signal transduction as well as other critical pathways of cell growth and survival.

CLINICAL CONSIDERATIONS

Disease Assessment and Prognostic Considerations

Conventional staging criteria, such as the tumor, node, metastases (TNM) staging system, do not describe the extent of disease beyond a simple anatomic classification, and they are not very helpful in the management of patients with recurrent or advanced prostate cancer. Treatment practices have resulted in the creation of different disease states as described by Scher and colleagues (2008). This system of “clinical states” allows classification of patients into a more relevant fashion and is increasingly being used throughout the literature. Figure 121-1 illustrates the natural history of prostate cancer relative to treatment practices and identifies the various clinical states according to the response status to different therapies. Throughout this chapter, prognostic and therapeutic considerations are largely based on the concepts proposed by this classification model.

A complete disease evaluation is required to estimate the prognosis and to make therapeutic decisions. Critical baseline components should also be considered, including extent of disease, mode and site of progression (rising prostate-specific antigen [PSA] level alone, new bone metastasis, visceral and nodal metastasis), presence or absence of symptoms including bone pain, and response to previous endocrine treatment. Regular monitoring with serial bone scintigraphs and CT scans together with serum PSA levels provides important information in patients demonstrating evidence of disease progression while they are receiving hormone therapy. Usually the first manifestation of disease progression after hormone therapy is a rising serum PSA level. In patients with metastatic disease, a rise in serum PSA level precedes evidence of advancing disease on the bone scan, and during this time patients may remain relatively asymptomatic (Eisenberger et al, 1995). Routine evaluation of serum testosterone levels may provide important information for the choice of subsequent treatment. This is especially

important when there might be reasons to suspect treatment non-compliance or if the choice of previous treatment involved regimens known not to result in a sustained suppression of serum testosterone to castrate levels (e.g., monotherapy with nonsteroidal antiandrogens, low-dose estrogens, or 5 α -reductase inhibitors).

For several years, it was postulated that discontinuation of androgen suppression in patients who have not undergone orchiectomy may adversely influence the outcome of their disease in terms of progression and survival (Taylor et al, 1993). Similarly it has been shown that administration of exogenous testosterone and its derivatives may indeed produce a significant clinical flare resulting in severe pain and neurologic, urologic, and coagulation complications in a small proportion of patients (Fowler and Whitmore, 1981; Manni et al, 1988). In a retrospective analysis of 205 patients with castration-resistant disease treated with chemotherapy, Hussain and associates (1994) evaluated various prognostic variables including orchiectomy. A multivariate analysis failed to indicate a significant correlation between previous orchiectomy and improved progression-free and overall survival. In these patients, all medical forms of androgen deprivation were discontinued at least 4 weeks before initiation of chemotherapy and, contrary to that suggested by Taylor and colleagues (1993), this did not significantly affect outcomes. Until this issue is resolved, the general consensus is to maintain all patients on luteinizing hormone-releasing hormone (LHRH) agonists or antagonists indefinitely, even during the course of subsequent therapies including chemotherapy. Indeed virtually all clinical trials that test novel therapies for men with CRPC mandate the continued suppression of serum testosterone levels, either with chronic ADT or with surgical castration.

Another important management aspect relates to antiandrogen withdrawal effects (Scher and Kelly, 1993; Small et al, 2004). Discontinuation of antiandrogens (both steroidal and nonsteroidal) can result in short-term clinical responses expressed by decreases in PSA levels, symptomatic benefits, and (less frequently) objective improvements in soft-tissue and bone metastasis in a small proportion of patients. Because of this phenomenon, it has been recommended that in patients who appear to be progressing while on antiandrogens in combination with other forms of androgen deprivation (e.g., LHRH agonists), the first step should involve the carefully observed discontinuation of the antiandrogen including serial monitoring of PSA levels for a period of 4 to 8 weeks before embarking on the next therapeutic maneuver.

The subsequent step is to determine which modality of treatment should be used next, either administration of second-line hormonal manipulation (including novel AR-directed therapies) or cytotoxic chemotherapy. There is an increasing body of data on

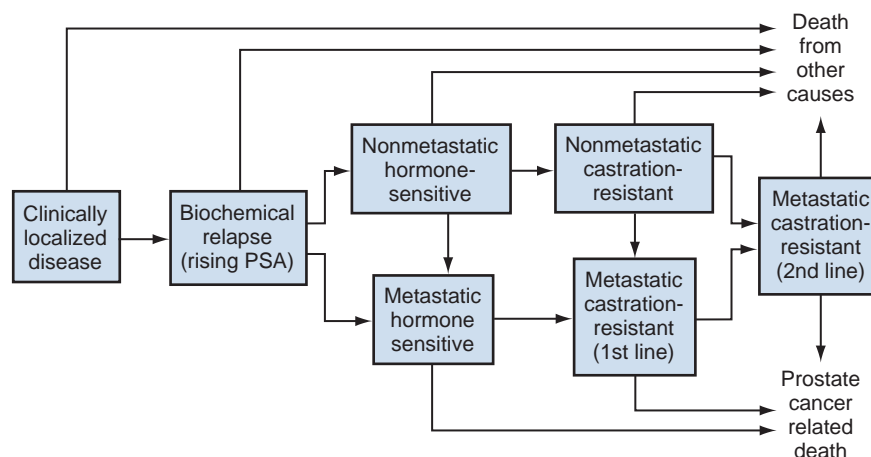

Figure 121-1. Prostate cancer clinical states. PSA, prostate-specific antigen. (Modified from Scher HI, Halabi S, Tannock I, et al. Design and end points of clinical trials for patients with progressive prostate cancer and castrate levels of testosterone: recommendations of the Prostate Cancer Clinical Trials Working Group. *J Clin Oncol* 2008;26:1148–59.)

second-line endocrine therapies suggesting that there may be a role for this approach before institution of chemotherapy (Small et al, 2004; Ryan, 2006; Ang et al, 2009). Although initial response rates to the second-generation hormonal manipulations range between 20% and 60%, the median duration of such responses is short, ranging between 2 and 4 months. Agents that have been reported to produce some benefit in this setting include diethylstilbestrol (Smith et al, 1986), aminoglutethimide (Sartor and Myers, 1995), ketoconazole (Small et al, 2004), as well as corticosteroids (Storlie et al, 1995). Since around 2012, additional next-generation AR-targeting therapies have become available (e.g., abiraterone and enzalutamide) and have largely replaced the second-generation endocrine agents listed earlier. In view of the potential higher toxicity profile associated with cytotoxic chemotherapy, a sequential hormonal approach may be a reasonable alternative for those patients with relatively limited metastatic disease who remain asymptomatic at the time of disease progression (e.g., rising serum PSA value without other clinical manifestations or pain).

Another important consideration is the initial clinical assessment of the potential biologic behavior of these tumors when they become castration resistant. Evolving data evaluating the role of PSA dynamics suggest that the PSA doubling time (PSADT) predicts the rapidity of bone scan progression and survival (D'Amico et al, 2005; Armstrong et al, 2007; Robinson et al, 2008). Patients with PSADT shorter than 3 months have a particularly rapid clinical course and should possibly be considered for more aggressive management approaches. Similarly, patients with symptomatic bone pain or visceral-predominant disease might be better served with cytotoxic chemotherapy upfront. In addition, poorly differentiated and neuroendocrine tumors usually have a low likelihood of significant and durable responses to further AR-directed therapies. The anaplastic/neuroendocrine phenotype is rare and requires special therapeutic considerations (see later). It has been suggested that systematic biopsies of disease sites in patients with clinically aggressive disease and relatively low serum PSA levels may demonstrate evidence of a neuroendocrine phenotype by immunostaining, which may be of prognostic and therapeutic significance. The usefulness of systematic biopsies in all patients with extensive metastasis and relatively low PSA levels, however, needs to be better defined before routine clinical application.

Nonmetastatic Castration-Resistant Prostate Cancer

The extraordinary stage migration that has affected all stages of prostate cancer has profoundly modified the spectrum of the clinical presentation of patients with castration-resistant disease. An increasing number of patients now begin androgen-deprivation therapy (ADT) at very early stages of their disease course, often at the first sign of a rising PSA following local therapy, before clinical and radiologic evidence of metastasis is present. This group of patients, termed the M0 (nonmetastatic) castrate-resistant subset, is now seen in increasing proportions in the clinic. Given the changes in treatment practices with early initiation of androgen deprivation, it is conceivable that these numbers will continue to increase. At this time data on the natural history of these patients are evolving, but the strongest predictor of metastatic progression appears to be the PSA kinetics (PSA velocity, PSADT).

A number of clinical trials using second-line hormonal manipulations and noncytotoxic interventions (bone-targeted treatments) focusing on time to development of bone metastasis have provided some useful information. A report of 201 patients from a prospective clinical trial comparing the effects of the bisphosphonate zoledronate versus placebo in men with M0 castrate-resistant disease suggested that the time to radiographic metastasis may be very long. At 2 years, only 33% of these patients exhibited evidence of bone metastasis, with a median time to bone metastasis in this group of 30 months. The baseline PSA level (>10 ng/mL) and the PSA velocity independently predicted time to bone metastasis and survival (Smith et al, 2005). In a retrospective review of a similar group of patients who were prescribed ADT before the development of metastatic disease, the median time to clinical metastasis was 9 months.

The pretreatment PSA level and the PSA nadir on ADT predicted metastasis-free survival (Dotan et al, 2005). The wide difference observed with these two reports (30 months vs. 9 months for time to bone scan metastasis) underscores the heterogeneity of this group of patients and the need for careful prospective evaluation. Their outcome is dependent on various factors, among which are pre-ADT characteristics (pretreatment PSA level, PSADT, initial stage, Gleason score), as well as differential response to hormonal treatment. However, it is probable that the risk of metastatic progression might be best estimated by PSA kinetics constructs such as PSADT and PSA velocity.

At present there is no consensus regarding the most appropriate management for patients with nonmetastatic CRPC, although the sequential endocrine approach (using second-generation agents, e.g., ketoconazole) is the most commonly used therapeutic modality. It must be highlighted that there are currently no U.S. Food and Drug Administration (FDA)-approved drugs specifically indicated to treat men with M0 CRPC disease. This, in turn, creates a unique opportunity for drug development in this setting. To this end, a number of placebo-controlled phase III trials are currently underway to test novel AR-directed therapies in men with nonmetastatic CRPC who are at a high risk for developing radiographic metastases. In summary, more data are needed to characterize the natural history and to define the best treatment approach for the M0 CRPC subset, which represents an important evolving new paradigm.

Metastatic Castration-Resistant Prostate Cancer

Patients with mCRPC represent a heterogeneous population with respect to their clinical and disease characteristics at the time of disease progression on ADT. Metastatic prostate adenocarcinoma has an overwhelming predilection to involve the bone. Although the explanation for this unique metastatic pattern has not been completely elucidated, it may reflect the combination of various biologic factors (tumor-specific and host-specific) present at the time of metastatic spread. Circulating prostatic adenocarcinoma cells are arrested in the cortical and medullary bone spaces, where they subsequently adhere to bone surfaces through specific receptors for moieties such as integrins, collagens, laminin, and other bone-derived proteins. Cell growth is subsequently promoted by a number of factors such as hormones, growth factors, and stromal-epithelial interactions, most of which operate in the bone marrow. Expansion of tumor cells in the bone may cause pain, compression of spinal nerves or the spinal cord, or pathologic fractures. In addition, extensive bone marrow replacement may cause impairment in hematologic function (most often manifested as myelophthytic anemia and thrombocytopenia).

Clinical involvement of visceral sites (excluding lymph nodes) is less common, even in patients with widespread castration-resistant disease. Even more rare is the occurrence of visceral disease in the absence of any bone involvement. Data from prospective clinical trials involving men with mCRPC suggest that radiographic evidence of visceral metastasis is observed in fewer than 20% of patients, whereas about 30% to 40% have demonstrable soft-tissue nodal disease. Because the majority of tumor burden in metastatic prostate cancer is found in bone, responses to treatment (e.g., tumor shrinkage) in soft-tissue sites alone (e.g., nodal or visceral sites) might not reflect a major treatment benefit because it represents only a small proportion of the overall disease burden. For this reason, the evaluation of "response rate" as the primary end point in clinical trials of mCRPC is discouraged, and "progression-free survival" (PFS) (that takes into account radiographic progression of bone and/or soft-tissue disease) is a much more acceptable trial end point (Scher et al, 2008).

Patients with mCRPC may present with a range of hematologic deficiencies caused primarily by the disease or by its treatment. Anemia is the most common hematologic abnormality, which can be explained by a variety of factors, such as anemia of chronic disease, bone marrow invasion, blood loss, and, rarely, secondary to a microangiopathic hemolytic anemia usually associated with a consumption coagulopathy (disseminated intravascular

coagulation). A decrease in the red blood cell count of patients with advanced CRPC commonly results from a combination of factors, such as previous treatment with local irradiation of bone marrow (especially pelvic bones), systemic use of chemotherapy and radiopharmaceuticals, long-term androgen deprivation, as well as from extensive bone marrow invasion by a tumor resulting in substantial decrease in bone marrow reserves. The use of erythropoietin has been popular in the past. However, use of erythropoietin-stimulating agents has fallen out of favor and should be used with caution, because evidence is now mounting that these agents may increase mortality in cancer patients (Bennett et al, 2008). Thrombocytopenia (and, more rarely, leukopenia) is usually a complication of extensive radiation therapy or systemic chemotherapy. As an end-stage process, rapidly growing tumors with bone marrow involvement might result in pancytopenia. Thrombocytosis is also a nonspecific manifestation associated with many neoplastic conditions, including prostate cancer. However, clotting complications associated with thrombocytosis are rarely seen in men with prostate cancer, and treatment is not usually necessary.

Among the most important urologic sequelae of advanced prostate cancer is the development of obstructive uropathy. This complication, usually related to the primary disease or to pelvic/retroperitoneal adenopathy, can be devastating in terms of quality of life, and it may even present major therapeutic implications. In addition to an increased incidence of infection and pain, obstructed kidneys might critically impair renal function to a point where some chemotherapeutic agents (which depend largely on renal mechanisms for their clearance) cannot be safely used. In general, patients who are otherwise considered candidates for treatment with cytotoxic drugs are best managed by first relieving the obstruction either with placement of internal ureteral stents or by percutaneous nephrostomy tubes.

Finally, one of the greatest emergencies in oncology is the development of spinal cord compression (Sorensen et al, 1990). Because of the frequent involvement of vertebral bodies by metastatic prostate cancer, the incidence of cord compression is of particular concern (see later).

KEY POINTS: CLINICAL CONSIDERATIONS

- Evaluate the extent and aggressiveness of the disease before contemplating therapy.
- Realize that the critical determinants are presence or absence of radiographic metastases, biochemical versus clinical progression, and presence or absence of symptoms (e.g., pain).
- Understand that the presentation of mCRPC is heterogeneous, both in terms of distribution of metastatic sites and in terms of PSA kinetics (e.g., PSADT).
- Consider secondary hormonal manipulations before initiation of cytotoxic chemotherapy, especially in men with non-metastatic CRPC or in those who are asymptomatic.

CYTOTOXIC CHEMOTHERAPY

Evaluation of Treatment Efficacy

Measurement of therapeutic efficacy in the clinical trial setting for patients with advanced prostate cancer might be confounded by significant methodologic challenges. The most common metastatic site in these patients is bone, manifested by diffuse osteoblastic lesions that cannot be measured reliably by current methods (termed “nonmeasurable” disease). Soft-tissue or visceral metastatic sites that allow serial measurements (“measurable” disease) are uncommon and represent only a small fraction of the total metastatic burden of the disease. Selection of bidimensionally measurable disease sites to assess therapeutic efficacy with serial tumor measurements has been the subject of significant criticism, because

many patients may only harbor metastases in osseous sites. Furthermore, patients with soft-tissue metastasis (especially visceral metastases) are often considered a subgroup with biologic and clinical features distinct from those with bone-only metastases. As a result of these potential caveats, the evaluation of “response rate” as the primary end point in clinical trials of mCRPC has been discouraged, and the use of PFS (taking into account radiographic progression of bone and/or soft-tissue disease) has become a much more acceptable trial end point in instances where overall survival is not a feasible end point (Scher et al, 2008).

A number of prognostic models evaluating baseline and post-treatment characteristics have been developed to help dissect the heterogeneity of CRPC in the context of various cytotoxic and non-cytotoxic therapies (Smaletz et al, 2002; Halabi et al, 2003; Armstrong et al, 2007; Halabi et al, 2013b). Among numerous clinical and laboratory parameters with consistent prognostic significance across a range of therapeutic settings are the patient's functional status (performance status), presence of pain, baseline hemoglobin level, baseline PSA level, baseline alkaline phosphatase, baseline LDH level, extent of bone involvement (number of lesions or pattern/distribution of bone lesions), and presence of visceral disease. Quantitative methods to evaluate circulating tumor cell (CTC) numbers and various PSA constructs (e.g., >30% PSA reduction) are among the post-treatment parameters with the strongest prognostic significance (Scher et al, 2004; Armstrong et al, 2007; de Bono et al, 2008; Halabi et al, 2013a).

Preclinical observations have suggested that some drugs might reduce PSA secretion without affecting tumor growth, whereas other drugs may affect tumor growth without necessarily reducing PSA levels (Larocca et al, 1991; Eisenberger and Nelson, 1996; Seckin et al, 1996). Although these laboratory observations are likely to be clinically relevant, assays used to evaluate a separate drug effect on PSA secretion still require careful validation. A PSA consensus meeting developed by several leading investigators in the field generated initial guidelines with regard to the use of the PSA test for clinical trials in patients with CRPC (Bubley et al, 1999). These guidelines were updated and now also provide a consensus on the use of radiologic end points as well as clinical end points (e.g., pain) for the evaluation of men with advanced CRPC (Scher et al, 2008). Undoubtedly, new biomarkers are needed to enhance our ability to identify rapidly the active treatments for CRPC, and one such marker may be the enumeration of CTCs (both at baseline and after a period of treatment) (de Bono et al, 2008). Furthermore, evolving noncytotoxic and targeted therapies might require a new set of end points and identification of drug-specific intermediate biomarkers that reflect mechanism-specific biologic activity.

Clinical Trials of Cytotoxic Agents

Most of the chemotherapeutic agents available in oncologic practice have been used in patients with CRPC, either as single agents or in various combinations. Historical examples have included cyclophosphamide, 5-fluorouracil, estramustine, vinorelbine, etoposide, cisplatin, carboplatin, doxorubicin, mitoxantrone, paclitaxel, and docetaxel (Eisenberger, 1988). With the exception of docetaxel (and the related agent, cabazitaxel) and perhaps mitoxantrone, most other cytotoxic agents are no longer being used with frequency because they have not been associated with either symptomatic improvements or extension of survival. Evolving data with selected chemotherapy agents during the new millennium suggest that the survival of patients with advanced CRPC receiving first-line chemotherapy is now somewhere between 16 and 20 months (Petrylak et al, 2004; Tannock et al, 2004) as opposed to 6 to 12 months as previously described with historical agents (Eisenberger, 1988).

Mitoxantrone

A first step forward in the chemotherapeutic management of CRPC came with mitoxantrone. This agent, a semisynthetic anthracycline, had previously shown modest symptomatic benefits but with minimal evidence of objective antitumor activity (Osborne et al,

Figure 121-2. Overall survival in the TAX 327 study. (From Tannock I, DeWit R, Berry W, et al. Docetaxel plus prednisone or mitoxantrone plus prednisone for advanced prostate cancer. *N Engl J Med* 2004;351:1502–12.)

1983; Rearden et al, 1995). In addition, mitoxantrone appeared to have its maximal palliative effect in combination with low-dose corticosteroids (Moore et al, 1994). In two seminal prospective randomized trials of mitoxantrone plus prednisone versus prednisone alone (Tannock et al, 1996) or mitoxantrone plus hydrocortisone versus hydrocortisone alone (Kantoff et al, 1999), the combination resulted in significant improvements of various quality-of-life parameters, including pain, but survival was not significantly improved in either trial. These studies provided the justification for the U.S. FDA to approve mitoxantrone with prednisone in 1997 for patients with *symptomatic* CRPC. Even though the use of first-line mitoxantrone has significantly diminished with the advent of more effective chemotherapy agents (docetaxel and cabazitaxel; see below), mitoxantrone is still useful for patients with docetaxel- and cabazitaxel-refractory disease, or in those with a marginal performance status in which the more toxic taxane agents may not be well tolerated.

Docetaxel

The next significant advance in the use of chemotherapy for CRPC came with docetaxel, a member of the taxane family. This agent acts by inducing apoptosis in cancer cells through TP53-independent mechanisms that are thought to be a result of the inhibition of microtubule depolymerization and the blockade of antiapoptotic signaling. The induction of microtubule stabilization intracellularly through β -tubulin interactions causes guanosine triphosphate-independent polymerization and cell cycle arrest at the G₂M phase. In addition, docetaxel has been found to induce BCL2 phosphorylation in vitro, a process that has been correlated with caspase-3 activation and loss of its normal antiapoptotic activity. Unable to inhibit the proapoptotic molecule BAX, phosphorylated BCL2 may also induce apoptosis through this alternate pathway. However, additional mechanisms might also be important, such as CDKN1B (p27) induction and repression of BCL-XL. Finally, it has emerged that docetaxel may exert part of its therapeutic effect by impairing association of the cytosolic AR to microtubules, thereby disrupting the transport of the ligand-bound AR from the cytoplasm into the nucleus on board the microtubules (Zhu et al, 2010; Darshan et al, 2011).

Early data with docetaxel monotherapy initially suggested that this compound might have significant activity in prostate cancer even as a single agent (Friedland et al, 1999; Picus and Schultz, 1999; Beer, 2004). In 2004, docetaxel became the chemotherapy drug of choice for the treatment of mCRPC based on a large phase III randomized trial, termed TAX 327 (Fig. 121-2), which demonstrated superiority beyond the previous standard: mitoxantrone plus prednisone (Tannock et al, 2004). The TAX 327 study enrolled 1006 patients with no previous chemotherapy treatment and with stable pain scores into one of three study arms (all with concomitant prednisone 5 mg twice daily): mitoxantrone 12 mg/m² intravenously every 21 days; docetaxel 75 mg/m² intravenously every 21 days; or docetaxel 30 mg/m² intravenously every 7 days. Patients remained on androgen suppression (e.g., LHRH agonists or orchiectomy), but all other second-line hormonal agents were discontinued. The anticipated treatment duration was 30 weeks (i.e., 10 cycles of therapy) in all study arms, although more patients completed treatment in the every-3-week docetaxel group than in the mitoxantrone group because of differences in disease progression rates (46% vs. 25%). After a median follow-up of 20.7 months, overall survival in the every-3-week docetaxel group was 18.9 months (with a pain response rate of 35% and a PSA response of 45%), compared to weekly docetaxel at 17.3 months (and 31% and 48%), respectively. This translated into a 24% relative reduction in the risk of death (95% confidence interval [CI] 6% to 48%, *P* = .0005) using 3-weekly docetaxel (see Fig. 121-2). Meanwhile, patients on the mitoxantrone arm experienced a median survival of 16.4 months, a pain response of 22%, and a PSA response of 32%. The conclusion of the TAX 327 trial was that every-3-week docetaxel was superior to both weekly docetaxel and every-3-week mitoxantrone. This was a landmark study, because it showed for the first time that chemotherapy could improve survival in mCRPC patients.

Toxicity in the 3-weekly versus weekly docetaxel groups was notable because of an increase in hematologic events in the every-3-week group (3% neutropenic fever vs. 0%; 32% grade 3/4 neutropenia vs. 1.5%), but slightly lower rates of nausea and vomiting, fatigue, nail changes, hyperlacrimation, and diarrhea. Neuropathy was slightly more common in the every-3-week group (grade 3/4 neuropathy in 1.8% vs. 0.9% in the weekly group). Quality-of-life responses as measured by the FACT-P instrument did not differ

Figure 121-3. Overall survival in the Southwest Oncology Group 9916 study. (From Petrylak DP, Tangen CM, Hussain MH, et al. Docetaxel and estramustine compared with mitoxantrone and prednisone for advanced refractory prostate cancer. *N Engl J Med* 2004;351:1513–20.)

significantly between the two docetaxel schedules but were more favorable than in the mitoxantrone group.

The Southwest Oncology Group (SWOG) 9916 study was the second large phase III trial (Fig. 121-3) to evaluate docetaxel (Petrylak et al, 2004). In this study, 770 patients with progressive CRPC were randomly assigned to oral estramustine (280 mg three times daily) plus docetaxel (60 mg/m² IV every 21 days) versus mitoxantrone (12 mg/m² IV every 21 days) plus prednisone. Median overall survival in the SWOG 9916 study was longer in the docetaxel-estramustine group than in the mitoxantrone-prednisone group (17.5 vs. 15.6 months, $P = .02$), with a corresponding hazard ratio (HR) for death of 0.80 (95% CI 0.67 to 0.97) (see Fig. 121-3). Because of the high rate of thromboembolic events with estramustine, prophylactic low-dose warfarin and aspirin were added to that study arm. Similarly, 20% and 15%, respectively, of patients in the docetaxel-estramustine arm had grade 3/4 gastrointestinal and cardiovascular toxicities. Although comparisons between the docetaxel arms across these two seminal trials may not be appropriate because of differences in schedule, patient populations, and docetaxel dosing (60 mg/m² in SWOG 9916 and 75 mg/m² in TAX 327), it was concluded that estramustine is unlikely to add significantly to the activity of single-agent docetaxel. For this reason, and because of its thromboembolic toxicities, estramustine is currently only a historic remnant and is no longer generally used in the United States.

A number of experimental agents have been investigated in combination with docetaxel in an attempt to improve on the efficacy of single-agent docetaxel. However, the results of most phase III trials of docetaxel-based combination therapy have been disappointing. Although serum vascular endothelial growth factor (VEGF) levels correlate inversely with survival, antiangiogenic agents (bevacizumab, aflibercept, and lenalidomide) combined with docetaxel have not improved overall survival. Combinations of bone-targeted agents such as atrasentan, zibotentan, and dasatinib with docetaxel have also produced disappointing results. Finally, high-dose vitamin D (calcitriol) combined with weekly docetaxel also demonstrated no survival advantage beyond docetaxel alone. Potential reasons for the failure of docetaxel-based combination therapies include marginal activity of the agents that were combined with docetaxel, lack

of well-conducted randomized phase II trials before initiating phase III studies, as well as dose reductions of docetaxel that were often required as a result of overlapping drug toxicities (Antonarakis and Eisenberger, 2013).

Cabazitaxel

Until recently, effective life-prolonging therapies for men with docetaxel-refractory prostate cancer were lacking. This changed in 2010, when the FDA approved yet another chemotherapy agent, cabazitaxel, for the treatment of mCRPC based on the results of a pivotal randomized phase III (TROPIC) trial (Fig. 121-4). Cabazitaxel is a novel tubulin-binding taxane that differs from docetaxel and paclitaxel because of its poor affinity for P-glycoprotein, the adenosine triphosphate-dependent drug efflux pump (Paller and Antonarakis, 2011). In preclinical studies using cancer cell lines and mouse xenograft models, cabazitaxel was shown to be active in both docetaxel-sensitive tumors as well as in those with primary or acquired docetaxel resistance (Attard et al, 2006). The first hint of cabazitaxel's safety and efficacy in men with prostate cancer came during phase I testing, where cabazitaxel was administered by intravenous infusion every 3 weeks at escalating doses of 10 to 25 mg/m² (Mita et al, 2009). In that study, the principal dose-limiting toxicity (DLT) was neutropenia. Given the lack of cross-resistance between this agent and docetaxel, and based on early reports of favorable responses in men with CRPC from this phase I trial, a phase III trial was launched to evaluate its activity.

The safety and efficacy of cabazitaxel in patients with advanced prostate cancer were definitively evaluated in the TROPIC trial conducted in 146 institutions across 26 countries, which recruited 755 men with mCRPC who had progressed after docetaxel-based chemotherapy (de Bono et al, 2010). Of these, 377 patients were randomized to receive mitoxantrone 12 mg/m² intravenously every 3 weeks (with oral prednisone 10 mg daily), and 378 patients were assigned to receive cabazitaxel 25 mg/m² intravenously every 3 weeks (plus prednisone). After a median follow-up of 12.8 months, overall survival in men receiving cabazitaxel was 15.1 months compared to 12.7 months in men receiving mitoxantrone (HR 0.70, $P < .0001$) (see Fig. 121-4) (de Bono et al, 2010). Compared to

Figure 121-4. Overall survival in the TROPIC study. CI, confidence interval; HR, hazard ratio. (From de Bono JS, Oudard S, Ozguroglu M, et al. Prednisone plus cabazitaxel or mitoxantrone for metastatic castration-resistant prostate cancer progressing after docetaxel treatment: a randomised open-label trial. *Lancet* 2010;376:1147–54.)

mitoxantrone, cabazitaxel also significantly lengthened PFS (2.8 months vs. 1.4 months, $P < .0001$), extended time to PSA progression (6.4 months vs. 3.1 months, $P = .001$), increased radiographic tumor response rates (14.4% vs. 4.4%, $P = .0005$), and increased PSA response rates (39.2% vs. 17.8%, $P = .0002$). There were no differences between the two treatment arms with respect to pain responses or time to pain progression. The results of this study formed the basis for the FDA's approval of cabazitaxel plus prednisone in June 2010 for the second-line treatment of docetaxel-refractory mCRPC.

In subset analyses, the survival advantage of cabazitaxel persisted regardless of whether patients experienced measurable disease or pain, or whether progression had occurred while receiving docetaxel or following a treatment holiday. In addition, cabazitaxel's survival benefit was most pronounced for men with Eastern Cooperative Oncology Group (ECOG) performance status 0 to 1 (vs. 2), and for patients with disease progression within <3 months of docetaxel initiation (vs. ≥ 3 months of docetaxel initiation) (de Bono et al, 2010). The last observation implies that cabazitaxel may be effective even in men with truly docetaxel-refractory disease, providing clinical evidence that there may not be significant cross-resistance between docetaxel and cabazitaxel.

The most common serious adverse events related to cabazitaxel were hematologic, including greater than or equal to grade 3 neutropenia in 82% of patients (febrile neutropenia in 8%). Patients older than 65 years experienced a 6.6% higher rate of grade 3 neutropenia than younger patients. This degree of myelosuppression begs the question of whether a lower dose of cabazitaxel (e.g., 20 mg/m²) may have been more appropriate; a randomized phase III trial (PROSELICA) comparing the safety and efficacy of these two doses (25 mg/m² vs. 20 mg/m² every 3 weeks) is now being conducted. To this end, use of growth factor support should be strongly considered when administering cabazitaxel, especially in men more than 65 years of age or in those with poorer performance status, as reflected in several national guidelines (Mohler et al, 2010). Other nonhematologic toxicities included greater than or equal to grade 3 diarrhea (6%) and greater than or equal to grade 3 fatigue (5%). Diarrhea was more common in patients older than 65 as well as in

those with a history of previous radiation therapy. Encouragingly, although peripheral neuropathy (all grades) was observed in 14% of patients receiving cabazitaxel, only 1% of men developed grade 3 neuropathy (de Bono et al, 2010).

Given the activity of cabazitaxel in docetaxel-pretreated patients, it would be logical to evaluate cabazitaxel as first-line chemotherapy in men with CRPC. To this end, an international randomized phase III trial (FIRSTANA) of docetaxel versus cabazitaxel (20 mg or 25 mg/m²) in chemotherapy-untreated patients has completed accrual, and results are awaited. A separate phase II study (TAXYN-ERGY) is randomizing patients to first-line docetaxel versus first-line cabazitaxel, and this is allowing patients to switch to the alternative taxane agent if they do not achieve more than a 30% PSA decline within the first 4 cycles of chemotherapy. That trial is also collecting CTCs to examine the association between the AR and microtubules, in an effort to uncover mechanisms of response and resistance to taxane drugs.

KEY POINTS: CYTOTOXIC CHEMOTHERAPY

- Docetaxel is the standard first-line chemotherapy for mCRPC. It prolongs progression-free and overall survival, ameliorates pain, and improves quality of life.
- Toxicity of docetaxel includes myelosuppression, fatigue, peripheral edema, neurotoxicity, hyperlacrimation, and nail dystrophy.
- Cabazitaxel has emerged as a second-line chemotherapy option for patients with mCRPC who have had progressive disease during or after docetaxel treatment.
- Toxicity of cabazitaxel includes neutropenia (including febrile neutropenia) and diarrhea.
- Although it does not prolong survival, mitoxantrone has been approved to palliate symptoms associated with metastatic disease, and it is often used in patients who have previously received docetaxel and/or cabazitaxel, or in those who would not tolerate these agents.

Figure 121-5. Overall survival in the COU-AA-301 study. (From de Bono JS, Logothetis CJ, Molina A, et al. Improved survival from metastatic prostate cancer with abiraterone acetate. *N Engl J Med* 2011;364:1995–2005.)

NOVEL ANDROGEN RECEPTOR-DIRECTED APPROACHES

CYP17 Inhibition: Abiraterone and Other Agents

It has been recognized that the AR and ligand-dependent AR signaling commonly remain active and upregulated in men with castrate levels of testosterone (i.e., <50 ng/dL) (Debes and Tindall, 2004). Standard hormonal therapies such as LHRH agonists/antagonists inhibit gonadal androgenesis but do not affect androgen synthesis from adrenal or other extragonadal sources that may account for up to 10% of total androgen production. It has also been suggested that CRPC itself may produce intratumoral androgens autonomously (Mostaghel et al, 2007). In addition, overexpression of CYP17 has been demonstrated in tumors of men with CRPC (Stigliano et al, 2007). All of this laboratory evidence suggests that CRPC is not androgen-independent and often remains hormone driven, implying that further suppression of nongonadal androgen sources might yield therapeutic gains.

The novel agent abiraterone acetate is an oral selective inhibitor of cytochrome P450 isoform 17 (CYP17), an enzyme that has both 17,20-lyase and 17 α -hydroxylase activity, and is a key regulator of extragonadal androgen synthesis. Phase I/II studies using abiraterone in men with CRPC (both before and after docetaxel) showed a substantial number of PSA responses (PSA declines $\geq 50\%$) and also some partial radiologic responses in men with bony and soft-tissue metastases (Attard et al, 2008; Danila et al, 2010). Furthermore, abiraterone retains its activity even in patients with previous ketoconazole treatment (a weak CYP17 inhibitor) (Ryan et al, 2010). Common side effects of abiraterone include hypokalemia, hypertension, and pedal edema. These effects are explained by a syndrome of secondary mineralocorticoid excess, which improves with use of the mineralocorticoid receptor antagonist eplerenone or with the addition of prednisone, which blunts the ACTH drive. Importantly, patients receiving abiraterone must also continue treatment with an LHRH agonist/antagonist, whereas the clinical activity of single-agent abiraterone is largely unknown.

To evaluate conclusively the efficacy and safety of abiraterone in men with CRPC, a pivotal multicenter placebo-controlled blinded randomized phase III trial (COU-AA-301) was conducted in men with docetaxel-pretreated ketoconazole-naïve mCRPC (de Bono

et al, 2011). This trial randomized men (2:1) to receive either abiraterone 1000 mg daily plus prednisone 10 mg daily ($n = 797$) or placebo plus prednisone ($n = 398$). The trial met its primary end point, demonstrating a median overall survival of 14.8 months in the abiraterone arm and 10.9 months in the placebo arm (HR 0.65, $P < .0001$) (Fig. 121-5). In addition, when compared to placebo, abiraterone prolonged radiographic PFS (5.6 vs. 3.6 months, $P < .0001$), improved time to PSA progression (10.2 vs. 6.6 months, $P < .0001$), and produced more PSA responses (38% vs. 10%, $P < .0001$). Further analysis showed that abiraterone had significant benefits compared with placebo in terms of pain relief, patient-reported fatigue, delaying pain progression, and prevention of skeletal-related events (Fizazi et al, 2012; Logothetis et al, 2012). Based on the results of the COU-AA-301 study, the FDA has approved abiraterone plus prednisone in April 2010 for the treatment of patients with mCRPC who have received previous docetaxel chemotherapy. The recommended dose of abiraterone is 1000 mg daily by mouth.

Because of the success of abiraterone in the postdocetaxel setting, a second randomized phase III trial (COU-AA-302) targeting men with docetaxel- and ketoconazole-naïve CRPC was undertaken. This double-blind placebo-controlled study recruited asymptomatic or mildly symptomatic chemotherapy-naïve patients with mCRPC and randomized them (1:1) to receive abiraterone (1000 mg) and prednisone (10 mg daily) or placebo and prednisone. The coprimary end points of this trial were radiographic PFS and overall survival. The study demonstrated a statistically significant difference in PFS in favor of the abiraterone arm (HR 0.43, 95% CI 0.35 to 0.52, $P < .0001$), representing a 57% reduction in the risk of radiographic progression with abiraterone (Ryan et al, 2013). The study also showed a strong trend toward improved overall survival, and significantly delayed initiation of cytotoxic chemotherapy (26.5 months vs. 16.8 months). In the final analysis, overall survival strongly favored the abiraterone arm (HR 0.79, 95% CI 0.66 to 0.95, $P = .015$), reflecting a 21% reduction in the risk of death, but not meeting the prespecified significance level set by the O'Brien-Fleming rule (that required a P value of $< .0035$). Once again, abiraterone produced additional benefits in the predocetaxel setting, including improved patient-reported quality-of-life outcomes (Basch et al, 2013). Based on the results of the COU-AA-302 trial, the FDA expanded the label for abiraterone to encompass all

patients with mCRPC (i.e., including those who have not received docetaxel chemotherapy). Of note, abiraterone is not currently approved for patients with nonmetastatic CRPC, a setting in which ketoconazole is still often used.

Other agents that target the androgen signaling pathway through CYP17 inhibition are also in clinical development. Orteronel (TAK-700) has a similar mechanism of action to abiraterone; it is a nonsteroidal CYP17 inhibitor with potentially greater 17,20 lyase selectivity (i.e., impairing androgen synthesis preferentially over corticosteroid synthesis). Orteronel has been evaluated in two large placebo-controlled phase III trials (with prednisone in both arms) in men with mCRPC who were either chemotherapy-naïve or docetaxel-pretreated. In the international ELM-PC5 (postdocetaxel) trial, although orteronel produced a significant improvement in PFS (HR 0.76, 95% CI 0.65 to 0.89, $P = .0004$), the study did not meet its primary survival end point (HR for survival: 0.89, 95% CI 0.74 to 1.06, $P = .19$) (Dreicer et al, 2014) and orteronel did not gain FDA approval. Interestingly, in countries where abiraterone was not available postprogression, survival was significantly improved with orteronel; whereas in countries where abiraterone was already approved; survival was not impacted probably because of subsequent treatment with abiraterone after patients came off the study. The phase III prechemotherapy (ELM-PC4) study has fully enrolled, and was a randomized trial of orteronel/prednisone versus placebo/prednisone. In this trial, PFS and overall survival are the coprimary end points, and the final results are awaited.

Androgen Receptor Modulation: Enzalutamide and Other Agents

A slightly different AR-directed approach has focused on the development of next-generation antiandrogens that include advantages beyond the established agents in this class (bicalutamide, nilutamide, flutamide). One such drug is enzalutamide, a potent oral nonsteroidal AR antagonist (Chen et al, 2009). Importantly, enzalutamide remains a strong antagonist of the AR in the castration-resistant state, even in the setting of overexpressed or constitutively activated AR (Watson et al, 2010). Unlike other antiandrogens that may also function as partial AR agonists, enzalutamide does not

exhibit any measurable agonistic activity. In addition to acting as an AR blocker, enzalutamide also disrupts the translocation of the AR from the cytoplasm (where it is inert) into the nucleus (where it acts as a transcription factor), while also impairing binding of the AR to the transcriptional complex at the androgen-response elements of DNA (Tran et al, 2009).

A phase II study of enzalutamide (160 mg orally daily) in men with chemotherapy-naïve ($n = 65$) or taxane-pretreated ($n = 75$) mCRPC showed preliminary evidence of potent activity (Scher et al, 2010). In that trial, greater than or equal to 50% of PSA declines were seen in 62% and 51% of chemotherapy-naïve and taxane-pretreated patients, respectively; objective tumor responses were observed in 36% and 12% of men with measurable disease, respectively. Radiographic PFS was 6.7 months in the docetaxel-pretreated patients and greater than 17 months in chemotherapy-naïve patients. In addition, 49% of patients had a decrease in their CTC counts, from unfavorable (≥ 5 CTC/7.5 mL blood) to favorable (< 5 CTC/7.5 mL blood) counts. Side effects of enzalutamide were generally mild and included fatigue (27%) and nausea (9%). Rare seizures (3/140 patients) were also reported, probably mediated by a direct effect of antagonism of central nervous system γ -aminobutyric acid receptors. One potential advantage of enzalutamide rather than abiraterone is the lack of a requirement for concurrent corticosteroid administration. In fact, data suggest that enzalutamide might potentially be less active if administered together with prednisone, perhaps because of promiscuous activation of AR by prednisone or by direct agonism of the glucocorticoid receptor (Scher et al, 2013).

A pivotal placebo-controlled double-blind phase III study (AFFIRM), randomizing 1199 patients with docetaxel-pretreated ketoconazole-naïve CRPC to enzalutamide ($n = 780$) or placebo ($n = 390$), was conducted to examine the effect of enzalutamide on overall survival. Patients receiving up to 2 previous lines of chemotherapy (one of which must have contained docetaxel) were the target population. The trial showed a 4.8-month improvement in median survival with enzalutamide compared to placebo (18.4 months vs. 13.6 months, HR 0.63, $P < .0001$) (Fig. 121-6) (Scher et al, 2012). A survival benefit was observed in all prespecified subgroups, although less benefit was seen in those with ECOG performance status of 2, similar to what was observed in the abiraterone

Figure 121-6. Overall survival in the AFFIRM study. (From Scher HI, Fizazi K, Saad F, et al. Increased survival with enzalutamide in prostate cancer after chemotherapy. *N Engl J Med* 2012;367:1187–97.)

trials. Confirmed PSA declines of more than 50% were seen in 54.0% compared to 1.5% ($P < .0001$) of patients receiving enzalutamide and placebo, respectively. Median time to progression was 8.3 compared to 3.0 months in the two arms (HR 0.25, $P < .0001$). Side effects were minimal and included fatigue, diarrhea, and hot flashes. Seizures were observed in about 1% of enzalutamide-treated patients. Based on the results of the AFFIRM trial, the FDA approved enzalutamide in August 2012 for the treatment of mCRPC in patients who have previously received docetaxel-containing chemotherapy.

To evaluate the efficacy of enzalutamide in the prechemotherapy setting, the PREVAIL study was designed. This was a phase III double-blind placebo-controlled trial in 1717 chemotherapy-naïve patients with asymptomatic or minimally symptomatic mCRPC who were randomized (1:1) to oral enzalutamide or placebo. At the time of an interim analysis, the study met its coprimary end points of radiographic PFS and overall survival. Compared to placebo, treatment with enzalutamide in the prechemotherapy setting resulted in a 29% reduction in the risk of death (HR 0.71, 95% CI 0.60 to 0.84, $P < .0001$) and an 81% reduction in the risk of radiographic progression (HR 0.19, 95% CI 0.15 to 0.23, $P < .0001$) (Beer et al, 2014). Based on the results on the PREVAIL trial, there is now strong evidence to suggest that enzalutamide can be used in all patients with mCRPC, regardless of whether or not they have received docetaxel chemotherapy.

Another next-generation AR signaling inhibitor is ARN-509. This is a novel antiandrogen (similar to enzalutamide) that also functions as a pure antagonist of the AR, while also inhibiting AR nuclear translocation and DNA binding (Clegg et al, 2012). ARN-509 might include potential advantages over enzalutamide in that it does not cross the blood-brain barrier and it has not been associated with seizures. Early evidence of clinical activity was obtained from a phase I study in 30 patients with progressive CRPC who received continuous daily oral ARN-509 at doses between 30 and 480 mg; a maximum efficacious dose of 240 mg daily was selected for phase II testing (Rathkopf et al, 2013). Adverse events with ARN-509 included fatigue (47%), diarrhea (30%), headache (20%), and hot flashes (13%). A phase II study of ARN-509 was then conducted, which enrolled three separate patient cohorts: men with nonmetastatic CRPC, men with mCRPC, and men with abiraterone-pretreated mCRPC (Rathkopf et al, 2012). In all three cohorts, a significant proportion of PSA responses gave evidence to clinical activity (although these responses were less frequent in each successive cohort owing to more advanced disease). This agent is now being studied in the SPARTAN trial, which is a multicenter blinded randomized phase III study for patients with nonmetastatic CRPC, in which metastases-free survival has been selected as the primary end point. In this study, patients are being randomized (2:1) to either ARN-509 or to placebo. Notably, ARN-509 is the first agent in prostate cancer that seeks regulatory approval in the nonmetastatic (M0) CRPC setting.

KEY POINTS: NOVEL ANDROGEN RECEPTOR-DIRECTED APPROACHES

- There is mounting evidence that CRPC is not androgen-independent and continues to rely on androgen/AR signaling.
- Abiraterone is a CYP17 inhibitor that depletes adrenal and intratumoral androgens. It is approved for the treatment of mCRPC, both before and after chemotherapy.
- Enzalutamide is a novel AR signaling inhibitor that blocks the AR and prevents nuclear translocation and DNA binding. It was shown to improve survival in men with mCRPC both in the prechemotherapy and postchemotherapy settings.
- Additional CYP17-targeting agents (e.g., orteronel) and AR-targeting agents (e.g., ARN-509) are in clinical development.

IMMUNOTHERAPY

An alternative or complementary strategy for the treatment of prostate cancer involves the use of immune-active agents. Cancer immunotherapy refers generally to approaches that attempt to treat cancer by activating immune responses against malignant cells while overcoming tumor-induced tolerance (Drake, 2010). Although not traditionally considered a disease amenable to immune-directed therapies, prostate cancer might in fact be an ideal target for immunologic attack because it is a slow-growing disease (allowing a stimulated immune system the time to generate an antitumor response), and it produces several tissue-specific proteins that may serve as tumor antigens: these include PSA, prostatic acid phosphatase (PAP), and others.

Entraining the immune system to overcome tumor-induced tolerance is the goal of nearly every cancer vaccine program, and active immunotherapy with vaccination against tumor-specific antigens has been pursued in many different cancer models including prostate cancer. A variety of approaches have been used, including dendritic cell-based therapies, adjuvants such as granulocyte-macrophage colony-stimulating factor (GM-CSF), viral carriers, single-antigen or whole-cell vaccines, genetically modified tumor cell vaccines, and DNA plasmid vaccines. More recently, strategies incorporating costimulatory molecules, cytotoxic T-lymphocyte antigen-4 (CTLA-4) blockade, PD-1 blockade, and intracellular viral or bacterial mediators have also been developed (Blattman et al, 2002; Mapara and Sykes, 2004; Webster et al, 2005; Harzstark and Small, 2009; Drake, 2010).

In prostate cancer, several of these immunologic approaches have been under clinical investigation, the most important of which is sipuleucel-T (an autologous PAP-loaded dendritic cell vaccine), which has gained FDA approval for patients with asymptomatic or minimally symptomatic mCRPC. Other immunotherapies that have entered late-phase clinical development include the GVAX allogeneic recombinant whole-cell vaccine (which failed to meet its primary end point in phase III trials), the ProstVac-VF recombinant poxviral PSA vaccine (currently in phase III testing), and CTLA-4 inhibitory approaches including ipilimumab (also in phase III testing).

Sipuleucel-T

Sipuleucel-T (Provenge) is a personalized vaccine that is derived from autologous CD54+ dendritic cells, the major class of antigen-presenting cells, which are apheresed from individuals and processed with a recombinant fusion protein composed of PAP and GM-CSF. PAP was chosen based on its prostate cell membrane localization and the success of preclinical models using it to generate prostate-specific immune responses and autoimmune prostatitis. Mixed activity was initially reported in early-phase trials using sipuleucel-T in patients with CRPC. In a randomized phase II/III trial comparing sipuleucel-T against placebo in 127 asymptomatic men with mCRPC, there was no significant difference in time to disease and pain progression ($P = .052$), which was the primary study end point (Small et al, 2006). However, patients randomized to placebo could cross over to receive the active vaccine at the time of progression, whereas those initially randomized to receive the active vaccine were treated at their physician's discretion at the time of progression. A 3-year update of this trial suggested a statistically significant improvement in overall survival for those patients assigned to receive sipuleucel-T initially ($P = .01$). Post hoc analyses also suggested that the benefits of sipuleucel-T might be limited to the subgroup of men with tumor Gleason sums of 7 or lower. Although preparation and production of large-scale quantities of individually tailored vaccine can be challenging, this vaccine was well tolerated, with minimal infusion-related fevers and rigors being the predominant adverse events (Small et al, 2006).

A second phase II/III trial that randomized 98 men with asymptomatic CRPC to either sipuleucel-T or placebo also failed to show a statistically significant improvement in time to progression (the primary end point of this study). However, post hoc pooled

Figure 121-7. Overall survival in the IMPACT study. (From Kantoff PW, Higano CS, Shore ND, et al. Sipuleucel-T immunotherapy for castration-resistant prostate cancer. *N Engl J Med* 2010;363:411-22.)

analyses of these two trials ($n = 225$) did show an overall survival advantage, with median survival being 18.9 months in the placebo group and 23.2 months in the sipuleucel-T group (HR 0.67, 95% CI 0.49 to 0.91, $P = .01$) (Higano et al, 2009). However, because overall survival was not the primary end point in either of these two trials, the FDA (justifiably) did not grant approval of this treatment at that time.

To evaluate definitively the clinical usefulness of sipuleucel-T in a larger patient population, a pivotal multicenter double-blind placebo-controlled randomized phase III trial (IMPACT) was conducted in men with asymptomatic or minimally symptomatic mCRPC (Kantoff et al, 2010a), finally leading to the FDA approval of this agent in April 2010. In this trial, 512 patients were randomized (2:1) to sipuleucel-T or to placebo, and the study was powered to detect an overall survival advantage. Notably, this study did not enroll men with visceral metastases or those taking narcotics for cancer pain, and most patients (85%) were chemotherapy naive. Impressively, median overall survival was 25.8 months in the sipuleucel-T group versus 21.7 months in the placebo group (HR 0.78, $P = .03$) (Fig. 121-7), despite 64% of patients on placebo crossing over to receive salvage sipuleucel-T at the time of disease progression. In the subset of patients with previous chemotherapy exposure, overall survival trended in favor of sipuleucel-T, but this effect was not statistically significant. Therefore, although this immunotherapy is approved for all patients with asymptomatic or minimally symptomatic CRPC, it will likely provide its largest impact in the prechemotherapy setting. In addition, it should not be used in patients with visceral disease, or in those requiring narcotic analgesics for cancer-related pain.

Similar to previous studies with sipuleucel-T, the IMPACT study detected no difference in PFS or PSA/radiographic response rates between the two treatment arms. Some investigators attribute the discord between progression-free and overall survival to a possible class effect of immunotherapy agents relating to their mechanism of action, which is distinct from cytotoxic therapies. Problematic end points such as PFS in CRPC (which may be confounded by bone scan flare or delayed-onset effects) might perhaps be better addressed by revised guidelines using outcomes that are tailored to immunologic agents (Hoos et al, 2010). These new immune-related response criteria may help in the future development of

additional immunotherapy agents for prostate cancer and other malignancies.

Because of the notion that immunotherapies are likely to have their biggest impact in the early-disease setting, sipuleucel-T has also been tested in combination with ADT in men with nonmetastatic biochemically-recurrent prostate cancer (Antonarakis and Kibel, 2013). Although the immunologic data from this trial appear encouraging, the mature clinical results are still awaited. In addition, other trials are currently testing the combination of sipuleucel-T with other AR-directed therapies. For example, one trial is examining the combination and sequencing of sipuleucel-T with abiraterone in men with mCRPC. Another trial is evaluating the optimal combination and sequencing of sipuleucel-T with enzalutamide. Both of these studies have not yet produced mature results. However, it is likely that immunotherapies will routinely be combined with other standard prostate cancer therapies moving forward so as to maximize clinical outcomes, especially if these agents do not have overlapping toxicities.

ProstVac-VF

ProstVac-VF is a PSA-targeted poxviral-based vaccine approach that has been developed through a series of iterative preclinical and clinical studies. The final version uses a heterologous prime-boost strategy (vaccinia prime, fowlpox boost), and incorporates a DNA plasmid containing the PSA gene plus three costimulatory molecules serving to increase PSA-specific immune responses (Madan et al, 2009). This particular vaccine is not a personalized product, is relatively inexpensive to synthesize, and is administered by repeated subcutaneous injections throughout several months. Similar to the clinical experience with sipuleucel-T, a randomized phase II study using this immunotherapy product demonstrated improved overall survival (a secondary end point) among men with mCRPC who received ProstVac-VF compared to those receiving an empty-vector placebo (25.1 vs. 16.6 months, HR 0.56, $P = .006$), whereas there was no impact on the primary end point of PFS (Kantoff et al, 2010b). Following from these encouraging results, and recognizing that this class of agents might produce a survival benefit without altering radiographic progression, a multinational randomized phase III trial has been launched in which 1200 men with chemotherapy-naïve asymptomatic or minimally symptomatic mCRPC are allocated (1:1:1) to one of three treatment arms: ProstVac-VF administered alone, ProstVac-VF plus subcutaneous GM-CSF, or placebo. The primary end point of this pivotal trial is overall survival, and final results are awaited.

In addition, there has been considerable interest in combining ProstVac-VF with other standard prostate cancer therapies in earlier disease settings. In a completed phase II study involving 42 men with nonmetastatic CRPC, patients were randomized to ProstVac-VF, followed by nilutamide versus nilutamide, followed by ProstVac-VF (Madan et al, 2008). This study suggested an improvement in overall survival in men receiving ProstVac-VF before nilutamide rather than the opposite sequence (6.2 vs. 3.7 years, $P = .04$). Another randomized phase II trial currently compares the combination of ProstVac-VF plus enzalutamide versus enzalutamide alone in men with nonmetastatic biochemically recurrent prostate cancer. Finally a separate randomized phase II study compares ProstVac-VF plus enzalutamide versus enzalutamide alone in men with mCRPC. These studies help to elucidate the role of combination immunohormonal therapy in various prostate cancer clinical states.

Immune Checkpoint Blockade

Because of ongoing host immunologic pressures on evolving tumors, cancers have developed mechanisms to escape immune surveillance, effectively inducing a state of immune tolerance (Drake et al, 2006). One way to inhibit immunologic evasion by tumor cells is through the blockade of the immune checkpoint molecule CTLA-4 (cytotoxic T lymphocyte-associated antigen-4), thus preventing the normal attenuation of antitumor T-cell responses (Hodi, 2007). In murine prostate cancer models, CTLA-4 inhibition has

been shown to potentiate T-cell effects and to induce tumor rejection including at metastatic sites (Kwon et al, 1999).

Several clinical trials using the monoclonal anti-CTLA-4 antibody, ipilimumab, have been conducted in men with mCRPC. These include phase I and II studies of ipilimumab monotherapy, or therapy in combination with radiation (Small et al, 2007), as well as a phase I study combining ipilimumab with GM-CSF (Fong et al, 2009). Encouragingly, across a broad range of phase I and II studies, greater than or equal to 50% of PSA reductions have been observed in about 10% to 20% of prostate cancer patients, and radiologic tumor responses were seen in about 5% of men (Slovin et al, 2013), which is particularly noteworthy given that PSA and tumor responses were rarely reported in the immunotherapy trials with sipuleucel-T or other therapeutic vaccines. Common side effects of ipilimumab include fatigue (42%), nausea (35%), pruritus (24%), constipation (21%), and rash (19%). In addition, because CTLA-4 normally serves to attenuate autoimmunity, immunologic toxicities resulting from an unchecked immune response might occur. Such immune-related adverse events include colitis (15% to 20%), hepatitis (5%), adrenal insufficiency and other endocrinopathies (2%), dermatitis/vitiligo (2%), and even hypophysitis (1%) (Dillard et al, 2010; Drake et al, 2014).

Based on these encouraging phase II data, ipilimumab entered phase III testing in the pre- and postchemotherapy settings. The first trial to be completed was a placebo-controlled phase III study in 799 men with mCRPC who had previously received docetaxel-based chemotherapy: all patients received a low dose of immunostimulatory radiotherapy to a bone metastasis (8 Gy) followed by treatment allocation to either ipilimumab (administered intravenously every 3 weeks for 12 weeks, and then every 12 weeks thereafter) or matching placebo. In this trial, although treatment with ipilimumab was associated with superior PSA response rates (13.1% vs. 5.3%, $P = .001$) and improved PFS (HR 0.70, 95% CI 0.61 to 0.82, $P < .0001$), there was no statistically significant improvement in overall survival although there was a strong trend favoring the ipilimumab arm (HR 0.85, 95% CI 0.72 to 1.00, $P = .053$) (Drake et al, 2014). Patients without visceral disease experienced the greatest benefit from ipilimumab, as well as those patients with normal hemoglobin and alkaline phosphatase levels. A second predocetaxel placebo-controlled phase III study is currently underway and has completed enrollment of 600 patients. In this trial, men with asymptomatic or minimally symptomatic CRPC have been randomized to ipilimumab or placebo; overall survival is the primary end point of this study and the results are awaited.

KEY POINTS: IMMUNOTHERAPY

- Sipuleucel-T is the first therapeutic vaccine to be approved by the FDA for the treatment of any cancer, and it is indicated for men with asymptomatic or minimally symptomatic mCRPC without visceral metastases or cancer-related pain requiring narcotics.
- ProstVac-VF is a poxviral-based PSA-directed prostate cancer vaccine that is administered by subcutaneous injection. It is currently in phase III testing for men with asymptomatic or minimally symptomatic mCRPC.
- Ipilimumab shows promising clinical activity in men with mCRPC, although a large trial in docetaxel-pretreated patients narrowly missed its primary survival end point. Although ipilimumab is not currently FDA-approved for prostate cancer, an ongoing trial is evaluating ipilimumab in men with mCRPC who have not yet received chemotherapy.
- The future of prostate cancer immunotherapies is likely to involve their use in the early-disease setting, or in combination with other standard prostate cancer therapeutics (hormone therapy and radiotherapy).

TARGETED TREATMENTS

Rational Target Overview

An understanding of the basic biology involved in the pathogenesis and progression of prostate cancer provides the opportunity to identify potential therapeutic targets for this disease. In general terms, the first therapeutic opportunity is the demonstration of a mutation or functional dysregulation of a target. Simply targeting overexpressed proteins has been less effective than the specific targeting of mutations that drive the bulk of the tumor growth. However, with the exception of the AR, this scenario is rare in prostate cancer. The second goal is identifying target causality, indicating the importance of the target alone or in combination with other aberrations in reproducing the phenotypic findings of prostate cancer. Finally there should be evidence from preclinical models that inhibition of the target leads to tumor regression or quiescence, not just growth restriction.

In prostate cancer, the AR is one potential therapeutic target, although there are many others. Given the molecular complexity of the prostate cancer cell and the relatively poor understanding of the role of non-AR pathways in prostate cancer progression and metastasis, the simultaneous inhibition of multiple pathways remains a common strategy to induce sustained and clinically meaningful patient responses. In addition, although a prostate cancer stem cell has yet to be conclusively demonstrated, prostate cancer clearly progresses from an androgen-dependent tumor (with features similar to the luminal differentiated glands of the prostate) to an AR-independent tumor (that has features of adult stem cells, including antiapoptotic mechanisms, chemotherapy resistance, and reliance on non-AR-related pathways).

To this end, candidate pathways currently under evaluation as targets for prostate cancer treatment include phosphatidylinositol 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) signaling, epidermal growth factor receptor (EGFR) signaling, mitogen-activated protein kinase (MAPK) signaling, angiogenesis signaling, apoptosis signaling, hedgehog signaling, insulin-like growth factor receptor (IGF-1R) signaling, Src kinase signaling, endothelin signaling, and several others (Wozney and Antonarakis, 2014). However, therapeutic approaches targeting these pathways have been largely unsuccessful, with few exceptions. Here we will outline some of the most promising efforts relating to therapies targeting the Akt/mTOR pathway, angiogenesis, and MET signaling, as well as apoptotic pathways. This section provides an overview of these select pathways as they pertain to prostate cancer rational targets and the approaches that are currently being developed for therapeutic purposes.

Phosphatidylinositol 3-Kinase/Akt/Mammalian Target of Rapamycin Pathway

The PI3K/Akt/mTOR pathway is an important signaling cascade present in many different types of human cancer. This pathway has been linked to cell survival, differentiation, proliferation, growth, metabolism, migration, and angiogenesis. Normally, signaling via this pathway begins with the binding of a growth factor to a receptor tyrosine kinase resulting in downstream activation of PI3K. Alternatively, PI3K activation can occur via Ras through G-protein-coupled receptors. PI3K phosphorylates its substrate, phosphatidylinositol 4,5-bisphosphate (PIP2) to produce phosphatidylinositol 3,4,5-triphosphate (PIP3). PIP3 can proceed to bind to various signaling proteins and can initiate downstream signaling via Akt. This pathway is negatively regulated by the protein tyrosine phosphatase (PTEN) (often deleted in prostate cancer), which dephosphorylates PIP3 to PIP2 thereby terminating further signaling (Engelman, 2009; Courtney et al, 2010). The PI3K/Akt signaling cascade promotes cell survival and resistance to apoptosis through several different mechanisms, including interactions with the Bcl-2 family members BAD and BAX, nuclear factor- κ B (NF- κ B), and Mdm2. Also downstream of this pathway is the mTOR protein.

Activation of mTOR leads to increased protein synthesis through phosphorylation of ribosomal proteins and translation elongation factors. In this fundamental way, mTOR is an important modulator of cell growth. Multiple feedback loops and regulators control mTOR signaling, and the pathway integrates inputs from various metabolic, growth factor, and survival pathways (Dancey, 2010).

Laboratory data have provided compelling foundations for studying the role of inhibitors of PI3K and its downstream targets in prostate cancer. Taylor and colleagues (2010) performed genomic profiling of 218 primary or metastatic prostate cancers, integrating information about DNA copy number, mRNA expression profiles, and exon sequencing. A core pathway analysis showed that altered signaling in the PI3K pathway was present in nearly half of all primary prostate tumors and in virtually all metastatic tumors tested. About 40% of all cases demonstrated loss-of-function of PTEN through deletion, silencing mutation, or reduced expression. In contrast to many other cancers, activating mutations in the *PIK3CA* gene were rare. However, loss-of-function mutations in the regulatory subunits PIK3R1 and PIK3R3 were prevalent, suggesting another mechanism for constitutive activation of PI3K in prostate cancer (Taylor et al, 2010).

Despite these telling observations, attempts to target segments of the PI3K/Akt/mTOR pathway in prostate cancer patients have been modest. Studies of the mTOR inhibitors rapamycin, everolimus, and temsirolimus as single agents and in combination with the AR antagonist bicalutamide failed to demonstrate significant clinical activity in mCRPC (Amato et al, 2008; Nakabayashi et al, 2012; Armstrong et al, 2013). Nevertheless, based on preclinical data showing that mTOR inhibition can reverse chemotherapy resistance in PTEN-deficient prostate cancer cell lines, ongoing trials are examining the efficacy of combined treatment with mTOR inhibitors and docetaxel (Grunwald et al, 2002; Duran et al, 2012). Other novel mTOR inhibitors and combination therapies are also under investigation.

One possible explanation for the failure of single-agent mTOR inhibitors to show efficacy in prostate cancer is the hypothesis that mTOR blockade leads to feedback-driven upregulation of signaling molecules upstream in the PI3K pathway. Studies by Carver et al (2011) have demonstrated the existence of bidirectional crosstalk between PI3K signaling and AR signaling. For example, in a preclinical model, inhibition of the PI3K pathway resulted in activation of AR signaling in PTEN-deficient prostate cancer cells. Similarly, the AR antagonist enzalutamide appeared to upregulate Akt signaling by reducing levels of the regulatory phosphatase PHLPP (PH domain leucine-rich repeat protein phosphatase). Combined blockade with the dual PI3K/mTOR inhibitor, BEZ235, and enzalutamide led to reductions in tumor size in human prostate cancer xenograft models (Carver et al, 2011). This work provides a sound rationale for simultaneous targeting of both pathways.

Under this premise, BEZ235 is currently being studied in combination with abiraterone in men with advanced CRPC. A first-in-human phase I study (that enrolled patients with various solid tumors) showed that BEZ235 was tolerable, as no DLTs were observed at the doses tested. Frequently reported side effects were fatigue and gastrointestinal symptoms. A few tumor responses were seen; patients whose tumors demonstrated activated PI3K pathway signaling were the most likely to respond to treatment with BEZ235. Because of pharmacokinetic variability, the drug was reformulated to improve bioavailability, which initially delayed clinical development of this agent (Maira et al, 2008; Burris et al, 2010).

Efforts to develop the potent and specific Akt inhibitor, MK2206, are also seeking to capitalize on the preclinical observations that simultaneous AR blockade and PI3K pathway inhibition may be synergistic. Previous phase II studies of another putative inhibitor of Akt, perifosine, had been disappointing. However, correlative pharmacodynamic studies were not performed in perifosine-treated patients, and therefore it is unclear whether target inhibition was actually achieved in these studies (Posadas et al, 2005; Chee et al, 2007). Conversely, pharmacodynamic correlates to the phase I study that established the safety profile and maximum tolerated dose of MK2206 have confirmed its ability to target and inhibit Akt

in humans. The most frequent side effects of MK2206 are hyperglycemia, nausea, diarrhea, skin rash, and stomatitis (Yap et al, 2011). MK2206 is currently being investigated in conjunction with bicalutamide in a cooperative group trial enrolling men with PSA-recurrent prostate cancer after failed local therapy.

The pan-PI3K inhibitors BKM120 and PX-866 are also being tested in phase II trials of mCRPC. Both of these drugs potently inhibit wild-type and mutant class-I PI3K isoforms. Phase I studies have included very few patients with prostate cancer, although one man with mCRPC who received PX-866 experienced prolonged stable disease. Interestingly, although the two drugs are purported to have the same mechanism of action, their side effect profiles are distinct. DLTs on the PX-866 phase I study were primarily gastrointestinal symptoms, including diarrhea and transaminitis. During the phase I study of BKM120, similar gastrointestinal symptoms were seen, but the drug included additional toxicities such as rash, hyperglycemia, and neuropsychiatric effects (mood alterations, depression) (Bendell et al, 2012; Hong et al, 2012). As phase II trials move forward, attention to the correlative pharmacodynamic studies for these drugs is imperative. One such intriguing study combines BKM120 with enzalutamide.

Angiogenesis

Therapeutic strategies aimed at preventing the growth of tumor vasculature have yielded clinical benefits for patients with several types of cancers, most notably renal cell carcinoma. There is a strong preclinical basis for studying inhibitors of angiogenesis in prostate cancer, as this process appears to play an important role in prostate carcinogenesis and maintenance. One of the key factors in angiogenesis is hypoxia-induced factor-1 α (HIF-1 α), a transcription factor whose expression is regulated by oxygen levels and growth factor signaling. HIF-1 α controls expression of various genes including many that are involved in angiogenesis, such as VEGF. VEGF acts directly on endothelial cells to stimulate proliferation and to increase vascular permeability, forming the matrix on which neovascularization can occur. In this manner, both hypoxia-dependent and hypoxia-independent mechanisms can induce angiogenesis (Semenza, 2003). In prostate cancer, neovascularization is not only triggered by the hypoxic tumor microenvironment, but also by aberrant growth factor signaling. For example, prostate cancer cells may aberrantly express both the VEGF receptor and ligand. This suggests a dual role for this pathway involving both paracrine signaling that promotes angiogenesis as well as autocrine signaling that stimulates cell growth and proliferation (Ferrer et al, 1997, 1999).

Many drugs that inhibit VEGF signaling have been tested in prostate cancer, including several that have been FDA-approved for treatment of other solid tumors. The best known is bevacizumab, a humanized monoclonal antibody to VEGF. Bevacizumab was evaluated in a phase III cooperative group trial in patients with mCRPC. Participants were treated with docetaxel and either bevacizumab (15 mg/kg IV every 21 days) or placebo. More than 1050 patients were enrolled in the study. PFS improved in the bevacizumab arm (9.9 vs. 7.5 months, $P < .001$), but overall survival did not differ significantly between arms (22.6 vs. 21.5 months, $P = .18$) (Kelly et al, 2012). Grade-3 or higher toxicities were more common in the bevacizumab arm, as was treatment-related mortality. Serious adverse events attributed to bevacizumab included hypertension, gastrointestinal perforation/hemorrhage, mucositis, and pneumonitis. Based on the "negative" results of this study, the FDA has not approved bevacizumab for use in patients with advanced prostate cancer. Ongoing studies are evaluating its role in conjunction with a short course of ADT in the PSA-recurrent/nonmetastatic setting. It is also being studied in mCRPC patients in combination with the mTOR inhibitors everolimus and temsirolimus.

An alternative antiangiogenic strategy involves the use of the VEGF-trap molecule aflibercept. Aflibercept is a decoy receptor that binds circulating VEGF ligand, thereby preventing its association with cellular VEGF receptors. The drug was studied in a multinational phase III trial in symptomatic mCRPC patients. More than

1200 patients were randomized to receive docetaxel plus either aflibercept or placebo. In this trial, there were no significant differences in progression-free or overall survival, and toxicities were higher in the aflibercept arm (Tannock et al, 2013). The increase in toxicities in the interventional arm mimicked the higher rate of adverse events with the docetaxel-bevacizumab combination. Because of these negative findings, no further studies of aflibercept are planned in patients with prostate cancer.

Attempts to target VEGF signaling with small molecule inhibitors in men with prostate cancer have shown some promise in phase II studies, but only one of these agents (sunitinib) has entered phase III testing. Sunitinib is a promiscuous tyrosine kinase inhibitor that blocks VEGFR2 and platelet-derived growth factor- β . A phase III study was conducted in patients with mCRPC who progressed after docetaxel chemotherapy. In this trial, more than 870 men were randomized to single-agent sunitinib or placebo. Although PFS was superior for sunitinib (5.6 vs. 4.1 months, $P < .001$), there was no significant difference in overall survival compared to placebo (13.1 vs. 11.8 months, $P = .17$) (Michaelson et al, 2014). The results of this study also raise the question of whether an overall survival benefit may have been observed if sunitinib had been continued beyond radiographic progression in patients who were tolerating the drug well. This agent is not FDA approved for prostate cancer.

Despite the disappointing results from the aforementioned phase III trials, several drugs targeting angiogenesis in novel ways remain in clinical development. Perhaps the most promising of these is tasquinimod, a second-generation quinolone-3-carboxamide analogue. Tasquinimod inhibits angiogenesis by preventing the upregulation of HIF-1 α and the resultant aberrant VEGF expression. It also appears to induce expression of an endogenous anti-angiogenesis factor, thrombospondin-1. Through an alternative or complementary mechanism of action, the drug also inhibits S100A9, a protein involved in differentiation and cell cycle progression. Inhibition of S100A9 also prevents recruitment of myeloid derived suppressor cells (MDSCs), which are important players in the tumor microenvironment. MDSCs may participate in immune escape and other mechanisms by which tumors evade immunologic attack (Isaacs, 2010). A phase II study of tasquinimod was conducted in men with mCRPC who had not received chemotherapy. The primary end point was radiographic PFS at 6 months. More than 200 men were randomized (2:1) to receive tasquinimod or placebo. Median PFS was 7.6 months with tasquinimod versus 3.3 months with placebo ($P = .004$). The drug had minimal effects on PSA kinetics, and few men achieved a significant reduction in PSA. Common side effects of tasquinimod were fatigue, nausea, constipation, and anorexia. Grade-3 and higher toxicities included asymptomatic elevations in the lipase and amylase levels, anemia, and venous thrombosis (Pili et al, 2011). Based on these results, tasquinimod has advanced to a placebo-controlled randomized phase III trial for patients with similar characteristics to those in the phase II study. This trial will use overall survival and PFS as coprimary end points, and it has already completed the accrual of 1200 men with chemotherapy-naïve CRPC.

MET Signaling

The c-Met receptor tyrosine kinase has received considerable attention as a potential therapeutic target for many solid tumors, including prostate cancer. c-Met is the cell surface receptor for the hepatocyte growth factor (HGF). In normal tissues, stromal cells produce HGF, and signaling through c-Met occurs largely via paracrine mechanisms. HGF/c-Met signaling is thought to be important for many physiologic processes including embryogenesis, organogenesis, angiogenesis, wound healing, and repair of organ damage (Trusolino et al, 2010; Scagliotti et al, 2013). Activation of c-Met can lead to signaling via multiple signal transduction pathways, including Src kinase and the PI3K/Akt/mTOR and MAPK cascades. These pathways activate many cellular processes relevant to cancer, including proliferation, survival, and resistance to apoptosis. HGF/c-Met signaling also promotes invasiveness, motility, and metastasis

through changes in the structure of the cytoskeleton and altered integrin expression (Peters and Adjei, 2012).

Abnormal c-Met expression has been observed in a variety of human malignancies, including prostate cancer. Mechanisms responsible for aberrant c-Met signaling include gene amplification and chromosomal rearrangement. Activating mutations and alternative splice variants can also lead to overactive c-Met signaling (Jeffers et al, 1997; Peters and Adjei, 2012; Scagliotti et al, 2013). In prostate cancer, paracrine mechanisms are believed to be predominantly responsible for increased c-Met signaling (Knudsen and Edlund, 2004). High c-Met expression exists in approximately 50% of primary prostate tumors at diagnosis and has been universally observed in bone metastases (Knudsen et al, 2002). In vitro, many CRPC cell lines also express high levels of c-Met mRNA and protein, and they are responsive to HGF in a concentration-dependent manner (Knudsen and Edlund, 2004). Therefore, the relationship between AR signaling and c-Met expression has been investigated. To this end, the AR appears to regulate negatively c-Met expression by interfering with Sp1, a transcription factor that binds to the promoter region of the *c-MET* gene. In support of this hypothesis, high c-Met expression has been observed in castration-resistant xenograft models. These findings have led to the conclusion that expression of c-Met and signaling via the HGF/Met axis may be important for the progression of prostate cancer to the castration-resistant state (Verras et al, 2007).

In addition, the presumed importance of c-Met signaling in prostate cancer and its widespread expression in osseous metastases has led investigators to study inhibitors of this signaling pathway in patients with advanced prostate cancer. Although several Met-targeting strategies have been used, cabozantinib (XL184) is the most promising c-Met inhibitor in clinical development for the treatment of prostate cancer. It is an oral tyrosine kinase inhibitor that potently inhibits c-Met and VEGFR2 (as well as RET). In phase I testing, side effects with cabozantinib were manageable and included diarrhea, fatigue, decreased appetite, and rash. The main DLTs of this agent were hand-foot syndrome, mucositis, and elevations of liver enzymes (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) as well as lipase elevations. Clinical benefit was seen in a broad range of tumor types (Kurczok et al, 2011).

Based on the responses seen in this phase I study, an international phase II randomized-discontinuation trial was conducted in nine tumor types simultaneously, including a cohort of men with mCRPC. The dose selected for this phase II study was 100 mg daily. All patients received open-label treatment with cabozantinib during a 12-week lead-in stage, and the trial then randomized patients with stable disease at 12 weeks to cabozantinib or placebo. The study oversight committee suspended randomization after the lead-in stage after the accrual of 122 patients, because unprecedented improvements were seen on bone scans across multiple tumor types (including prostate cancer). At that point, median PFS in CRPC patients with cabozantinib was 23.9 weeks compared to 5.9 weeks with placebo (Smith et al, 2013). Ultimately, the study enrolled a total of 171 patients with mCRPC, almost half of whom had previously received chemotherapy. Although the partial radiographic response rate was only 5%, an additional 75% of patients had stable disease. As before, cabozantinib appeared particularly active in treating bone metastases, with 12% of patients showing complete resolution of disease on technetium-99 bone scan. Reductions in pain scores and narcotic use were also observed in a significant proportion of patients. Importantly, PSA changes did not correlate with the favorable results seen on imaging studies or other signs of clinical benefit; some patients exhibited rising PSA levels despite reductions in the size of soft-tissue lesions or bone metastases. The toxicity profile of cabozantinib in this study was similar to that reported in the phase I trial, although higher rates of grade-3 hypertension were seen (Smith et al, 2013).

Cabozantinib was studied in two phase III trials in men with mCRPC with progressive disease following treatment with docetaxel and a novel AR-directed agent (abiraterone or enzalutamide). The first study (COMET-1) evaluated the efficacy of single-agent

cabozantinib versus placebo, with a primary end point of overall survival. The second study (COMET-2) investigated the effect of cabozantinib versus mitoxantrone on quality-of-life measures and pain control; the primary end point of that study was the frequency of durable pain responses lasting at least 12 weeks (whereas overall survival was a secondary end point). These trials were considered the registrational studies for cabozantinib in advanced CRPC. Both studies failed to meet their primary end points.

Apoptosis Pathway

Another rational therapeutic approach for multiple cancer types including prostate cancer is the induction of tumor cell apoptosis. To this end, clusterin is a stress-induced antiapoptotic chaperone protein expressed in various cancers including prostate cancer (Zoubeidi et al, 2010), and it has received renewed attention because of the development of an antisense inhibitor to this protein. Importantly, expression of clusterin in prostate tumors increases after treatment with androgen ablation or chemotherapy (Miyake et al, 2000; July et al, 2002), conferring a more resistant phenotype. Custirsen is a novel intravenously administered antisense oligonucleotide moiety that inhibits clusterin at the mRNA level, increasing sensitivity to androgen deprivation as well as chemotherapy in prostate cancer cell lines and in xenograft models (Gleave and Miyake, 2005; Sowery et al, 2008).

In a randomized phase II trial of docetaxel administered with or without custirsen in 82 patients with mCRPC, PSA responses (58% vs. 54%) as well as PFS (7.3 vs. 6.1 months) were essentially similar in both arms. However, there was a trend in overall survival favoring the combination arm (23.8 vs. 16.9 months, $P = .06$), although survival was not the primary end point of this study, and confidence intervals around these estimates were wide and potentially confounded by subsequent therapies (Chi et al, 2010). Adverse events associated with custirsen in that trial included fatigue (48%), fever (30% to 50%), rigors (40% to 60%), diarrhea (40% to 60%) and rash (20% to 40%). Another phase II study of second-line chemotherapy plus custirsen in patients with docetaxel-pretreated CRPC has completed accrual, and outcomes are awaited.

Finally, two registrational placebo-controlled phase III trials of custirsen are underway. The first study (SYNERGY) randomized 1022 patients with chemotherapy-naïve mCRPC to receive standard docetaxel versus the combination of docetaxel plus open-label custirsen; overall survival was chosen as the primary end point in this trial. This study failed to meet its primary end point. The second study (AFFINITY) is currently randomizing 630 patients with docetaxel-pretreated CRPC to either cabazitaxel alone or cabazitaxel plus custirsen; the primary end point of this study is also overall survival. The overarching aim of these studies is to test definitively the hypothesis that clusterin inhibition may reverse chemotherapy resistance in CRPC.

KEY POINTS: NOVEL TARGETED TREATMENTS

- Despite negative studies with bevacizumab and aflibercept, angiogenesis remains a valid therapeutic target in prostate cancer, as exemplified by the novel agent tasquinimod.
- Because of the reciprocal interactions between the PI3K/Akt/mTOR pathway and the AR signaling pathway, dual inhibition of both pathways concurrently will likely represent the most fruitful therapeutic strategy.
- Cabozantinib is a novel small molecule inhibitor of c-Met and VEGFR2, with profound activity on CRPC bone metastases.
- Custirsen is an antisense oligonucleotide against clusterin mRNA, which may play a role in reversing resistance to taxane chemotherapies.

PALLIATIVE MANAGEMENT

Pain and Epidural Cord Compression

As in other disseminated malignancies, palliation of symptoms and maintenance of adequate quality of life represent the most important objectives in the management of advanced prostate cancer. Cancer-related pain is undoubtedly the most debilitating symptom associated with advanced-stage metastatic prostatic carcinoma. Prompt recognition of the various pain syndromes associated with this disease is critical to accomplish effective control of this devastating symptom. The most common pain syndromes and their respective therapeutic considerations are summarized in Table 121-1. Focal bone pain in patients with CRPC can be well controlled using external-beam localized radiation therapy. In general, it is also recommended that painful areas that are shown to be abnormal on bone scintigraphy should be evaluated with plain radiographs or CT imaging to exclude the presence of osteolytic lesions or pathologic fractures. Such considerations become even more important when the painful areas affect extremities and weight-bearing sites.

Epidural metastasis is fairly common and is a potentially devastating complication of systemic cancer. In view of the propensity for prostate cancer to metastasize to the vertebrae and paravertebral regions, the incidence of epidural cord compression is particularly high in this disease. Early diagnosis and treatment of epidural metastasis is critical in preserving ambulation and bowel and bladder function and aids in the management of back pain (Grossman and Lissignol, 1990; Gabriel and Schiff, 2004). Epidural cord compressions arising from vertebral bodies account for the majority of spinal cord compressions; less frequently they are associated with soft-tissue masses involving the paravertebral region. Most of these patients have abnormalities on bone scintigraphs and/or abnormal findings on radiography at the time of diagnosis. However, a deficit on neurologic examination may be the only finding in patients who exhibit soft-tissue epidural metastasis in the paravertebral region.

Spinal magnetic resonance imaging (MRI) is routinely used to exclude the possibility of significant epidural disease, and it has almost entirely replaced other methods such as CT myelography and conventional myelography. The first therapeutic intervention in patients with suspected or documented cord compression should include the administration of high doses of intravenous glucocorticoids. Dexamethasone at doses ranging from 16 to 100 mg daily is most commonly used. Patients are often administered an intravenous "loading dose" of 10 mg of dexamethasone followed by 4 to 10 mg every 6 hours; the optimal steroid dose remains relatively undefined. On improvement of symptoms, which can be accomplished promptly with glucocorticoids, the steroid dose may be tapered down throughout a 2-week to 3-week period.

Radiation therapy is often the mainstay of definitive treatment. However, reports suggest that decompressive surgery followed by radiation therapy may be superior to radiation therapy alone (Patchell et al, 2005). To this end, surgery should be considered in patients who present with evidence of progressive signs and symptoms during radiation therapy, develop or present with unstable pathologic fractures that require stabilization, or experience recurrence after radiotherapy. In addition, the overall prognosis of the underlying disease should be considered during the treatment selection. Chemotherapy is rarely used to treat epidural cord compression during the acute management of this complication.

Bone-Targeted Approaches

The pathogenesis of bone metastases in prostate cancer remains a subject of major study. Alterations in the normal process of bone absorption and formation, which usually follow an orderly and sequential path, appear to be a key determining factor in the development of bone metastasis associated with most malignant neoplasms (Roodman, 2004). Under normal physiologic conditions the process of bone remodeling is initiated by an increase in osteoclastic activity followed by an increase in osteoblastic differentiation and maturation, which results in the formation of new bone and

TABLE 121-1 Common Pain Syndromes in Metastatic Castration-Resistant Prostate Cancer

PAIN SYNDROME	INITIAL MANAGEMENT	OTHER THERAPEUTIC ALTERNATIVES
Localized bone pain	Pharmacologic pain management Localized radiotherapy (special attention to weight-bearing areas, lytic metastasis, and extremities)	Surgical stabilization of pathologic fractures or extensive bone erosions Epidural metastasis and cord compression should be evaluated in all patients with focal back pain Radiopharmaceuticals should be considered if local radiation therapy fails
Diffuse bone pain	Pharmacologic pain management “Multisite” or wide-field radiotherapy Radiopharmaceuticals	Corticosteroids Bisphosphonates or RANK ligand inhibitors Calcitonin Chemotherapy
Epidural metastasis and cord compression	High-dose corticosteroids Radiation therapy Surgical decompression and stabilization is indicated in high-grade epidural compressions, extensive bone involvement, or recurrence after irradiation.	Pharmacologic pain management Physical therapy for recovery of neurologic function
Nerve plexopathies caused by direct tumor extension or previous therapy (rare)	Pharmacologic pain management Radiation therapy (if not previously used) Neurolytic procedures (nerve blocks)	Tricyclic antidepressants (amitriptyline) Anticonvulsants (gabapentin, pregabalin)
Miscellaneous neurogenic causes: postherpetic neuralgia, peripheral neuropathies	Complete neurologic evaluation Pharmacologic pain management Discontinuation of neurotoxic drugs: docetaxel, platinum compounds	Tricyclic antidepressants (amitriptyline) Anticonvulsants (gabapentin, pregabalin)
Other uncommon pain syndromes: extensive skull metastasis with cranial nerve/skull base involvement, extensive painful liver metastasis, or pelvic masses	Radiation therapy Pharmacologic pain management Corticosteroids (cranial nerve involvement)	Chemotherapy Intrathecal chemotherapy may ameliorate symptoms of meningeal involvement

RANK, receptor activator of nuclear factor- κ B.

the repair of the initial absorption caused by osteoblasts. Bone loss associated with prostate cancer can result from an enhanced osteoclastic activity associated with long-term androgen suppression, which in turn can cause excessive resorption of bone mineral and organic matrix. Tumor cells may also cause mineral release and matrix resorption in the areas involved by metastatic disease (Galasko, 1986). In addition, various cytokines, growth factors, tumor necrosis factors, and bone morphogenic proteins have been shown in preclinical studies to play a major role in the induction of both osteoclastic and osteoblastic activity (Reddi and Cunningham, 1990). In prostate cancer, bone metastases are predominantly blastic, which reflects a predominance of osteoblastic activity in the process of bone remodeling (Roodman, 2004). This phenomenon may be a result of specific growth factor secretion that is responsible for the induction of osteoblasts. Unlike other bone-tropic malignancies, hypercalcemia is rare in metastatic prostate cancer. In fact, a significantly elevated serum calcium concentration is most frequently a result of the neuroendocrine prostate cancer phenotype (see later) and is mediated through parathyroid hormone-related protein (PTHrP) (diSant’Agnese, 1995; Nelson et al, 2007).

Bisphosphonates

Bisphosphonates have become an integral part of the management of metastatic prostate cancer involving the bones (Van den Wyngaert et al, 2009). These compounds reduce bone resorption by inhibiting osteoclastic activity and proliferation. Zoledronate is a

potent intravenous bisphosphonate first approved for the treatment of hypercalcemia and decreased bone mineral density in postmenopausal women (Green and Rogers, 2002). In patients with progressive CRPC and bone metastases, zoledronate was shown to reduce the incidence of skeletal-related events (e.g., pain, fractures) compared with placebo in a prospective randomized trial of 422 patients (Saad et al, 2004). In addition, zoledronate and pamidronate have also been shown to increase bone mineral density in patients with nonmetastatic prostate cancer receiving long-term androgen deprivation (Smith et al, 2001, 2003).

At present, zoledronate is indicated for the treatment of patients with progressive CRPC with evidence of bone metastasis, and it is administered at a dose of 4 mg intravenously repeated at intervals of 4 weeks for several months. Side effects of this agent include fatigue, myalgias, fever, anemia, and mild elevation of serum creatinine. Hypocalcemia has been described with the use of zoledronate, and concomitant administration of oral calcium supplements (1000 mg/day) and vitamin D (800 units/day) is often recommended. An unusual complication of zoledronate is the development of severe jaw pain associated with osteonecrosis of the mandibular bone (called osteonecrosis of the jaw [ONJ]). The etiology of this phenomenon is not well understood. However, it is most frequently seen in patients undergoing dental work or those with a history of poor dentition and chronic dental disease. Zoledronate should not be administered to patients with these problems. Other bisphosphonates have also been evaluated in prostate cancer, including alendronate, etidronate, ibandronate, and clodronate;

however, their benefit has not been conclusively established in prospective randomized clinical trials (Berry et al, 2006; Van den Wyngaert et al, 2009).

Receptor Activator of Nuclear Factor- κ B Ligand Inhibitors

Interactions between tumor cells and the bone marrow microenvironment have been postulated as an additional important mechanism in the pathogenesis of bone metastasis. Tumor-associated cytokines have been shown to induce the expression of the receptor activator of nuclear factor- κ B ligand (RANKL) that binds and activates RANK, which is found in osteoclasts (Brown et al, 2001). Inhibition of the RANKL system has been the focus of much research and represents an evolving bone-targeted strategy. Among the approaches used are monoclonal antibodies to RANKL and the use of recombinant osteoprotegerin (the natural decoy receptor of RANKL), both of which significantly inhibit osteoclastic function in vitro and in vivo (Schwarz and Ritchlin, 2007). Denosumab, a fully human monoclonal antibody against RANKL, was the first agent to enter clinical trials in patients with prostate cancer as well as breast cancer. In a phase II randomized study evaluating 50 patients with metastatic prostate cancer, denosumab (administered subcutaneously every 4 weeks) produced a reduction in bone resorption beyond that of zoledronate, as indicated by a lowering of urinary *N*-telopeptide levels, and it also resulted in fewer skeletal-related events (Fizazi et al, 2009).

Following from these encouraging results, a pivotal multicenter phase III double-blind randomized study was conducted comparing denosumab against zoledronate for the prevention of skeletal-related events in patients with bisphosphonate-naïve mCRPC. In that trial of 1904 patients, compared to men receiving zoledronate ($n = 951$), men receiving denosumab ($n = 950$) showed an improved time-to-first skeletal-related event (20.7 vs. 17.1 months, $P = .008$) and a longer time to first-and-subsequent skeletal-related events (HR 0.82, $P = .004$) (Fizazi et al, 2011). Notably, there was no difference in overall survival or PFS between study arms. Based partially on the results of this study (and partially on two other large randomized studies in metastatic breast cancer and other solid metastatic tumors), the FDA approved denosumab in November 2010 for the prevention of skeletal-related events in patients with bone metastases from solid tumors. Common toxicities of denosumab include fatigue, nausea, hypophosphatemia, and hypocalcemia (grade ≥ 3 in 5% of patients). ONJ also occurs in about 2% to 4% of patients, and prophylactic use of calcium and vitamin D supplementation is strongly encouraged. Therefore, denosumab is a reasonable alternative to zoledronate for the prevention of skeletal-related events in patients with mCRPC, and it also includes an advantage in that it does not require dose adjustment or monitoring for renal impairment. The recommended dose of denosumab is 120 mg administered by subcutaneous injection every 4 weeks.

Radiopharmaceuticals

The introduction of “bone-seeking” radiopharmaceuticals has provided a useful resource for the management of diffuse bone pain from widespread prostate cancer metastases (Pandit-Taskar et al, 2004) and it might even improve survival (Parker et al, 2013a). Historically the most commonly used compounds were the beta emitters strontium-89 (^{89}Sr) (Porter et al, 1993) and samarium-153 (^{153}Sm) (Sartor et al, 2004), although these agents will largely be replaced by the alpha emitter radium-223 (^{223}Ra). Initial studies with ^{89}Sr showed palliation of bone pain in 25% to 65% of patients with CRPC and diffuse bone pain (Jager et al, 2000). The pharmacokinetics of ^{89}Sr vary considerably according to the extent of bone involvement, but the half-life is generally 4 to 5 days. The retention of this isotope is significantly longer in patients with diffuse osteoblastic metastases compared to those with relatively limited bone involvement. It is important to recognize this factor because it affects the degree and duration of myelotoxicity associated with this radioactive compound (its most significant toxicity). The clinical experience with ^{153}Sm suggests that this isotope is associated with

a lower incidence of myelotoxicity, probably because of its shorter half-life of 2 days. Encouraging results were reported by Sartor and colleagues (2004) in a phase III trial comparing radioactive ^{153}Sm and nonradioactive ^{152}Sm , indicating that a dose of ^{153}Sm of 1 mCi/kg is both safe and effective palliation for patients with CRPC and severe bone pain. However, although ^{89}Sr and ^{153}Sm are both FDA approved for the palliative management of castration-resistant bone metastases, neither compound was demonstrated to provide a survival advantage. To this end, the novel alpha-emitting agent radium-223 will probably replace these beta emitters because of its capacity not only to palliate bone pain but also to improve overall survival in this setting.

Radium-223 is a novel alpha-emitting radiopharmaceutical that has received significant attention. Alpha particles are approximately 7000 times heavier than beta particles, and as few as one or two hits can be sufficient to cause cell death, in comparison with hundreds or thousands of hits required from beta particles. In addition, alpha particles have a very short path length ($<100\ \mu\text{m}$), which may spare surrounding healthy bone marrow, thereby limiting hematologic toxicities (Henriksen et al, 2003). A series of phase I and II trials demonstrated the safety of radium-223, together with evidence of biologic activity in terms of serum markers of bone turnover and PSA changes, and also raised the possibility that treatment with radium-223 might improve overall survival (Nilsson et al, 2005, 2007, 2012; Parker et al, 2013b).

These promising early-phase data led to the design of the phase III ALSYMPCA trial (Parker et al, 2013a), as a result of which radium-223 gained FDA approval for use in mCRPC patients with symptomatic bone metastases. This was an international, randomized, double-blind, placebo-controlled phase III study comparing best standard care plus radium-223 versus best standard care plus placebo in men with mCRPC who were chemotherapy-refractory or chemotherapy-ineligible. Enrollment was restricted to men with symptomatic bone metastases in the absence of known visceral disease or bulky lymph-node metastases. Radium-223 was administered at a dose of 50 kBq/kg (intravenously) every 4 weeks for a total of 6 doses. The primary end point of this trial was overall survival, which was improved by radium-223 compared to placebo (HR 0.70, 95% CI 0.58 to 0.83, $P < .001$); this translated into a median survival benefit of 3.6 months beyond placebo (Fig. 121-8) (Parker et al, 2013a). In addition, all of the secondary efficacy end points were also met, with a 6-month delay in median time-to-first symptomatic-skeletal event (HR 0.66, 95% CI 0.52 to 0.83, $P < .001$), and a significant improvement in quality of life measured using the FACT-P scale. Remarkably, the incidence of adverse events and serious adverse events was lower in the radium-223 group than in the placebo group. Diarrhea was the most common side effect in ^{223}Ra -treated patients. Hematologic toxicity was rare (e.g., grade 3/4 thrombocytopenia was seen in 6% of men receiving radium-223 vs. 2% for placebo). Based on the results of the ALSYMPCA trial, radium-223 would be a reasonable treatment choice for any patient with symptomatic bone-mCRPC without visceral or bulky nodal metastases. This agent may be used both in docetaxel-refractory patients and in those who are ineligible or uninterested in receiving chemotherapy.

THE NEUROENDOCRINE/ANAPLASTIC PHENOTYPE

Laboratory and clinical evidence indicates that alterations in the differentiation pathway of prostate cancer can be seen in a small proportion of patients with advanced-stage disease, giving rise to a neuroendocrine/anaplastic transformation (diSant'Agnese, 1995; Nelson et al, 2007). The therapeutic implications of this finding are of significance because tumors demonstrating this phenotype usually represent an inherently endocrine-resistant subtype and, in view of their different clinical and biologic properties compared with the usual adenocarcinoma of the prostate, these tumors also require different treatment strategies.

Such tumors possess a number of biologic characteristics unique to neuroendocrine tumors that can also arise from other organs,

Figure 121-8. Overall survival in the ALSYMPCA study. (From Parker C, Nilsson S, Heinrich D, et al. Alpha emitter radium-223 and survival in metastatic prostate cancer. *N Engl J Med* 2013;369:213–23.)

KEY POINTS: PALLIATIVE MANAGEMENT

- Patients with back pain and a history of bone metastases should be evaluated for epidural cord compression. The clinical syndrome often includes at least one of the following signs and symptoms: back pain, focal neurologic deficit (leg weakness, sensory levels), or changes in bladder or bowel control.
- Initial management of suspected cord compression includes immediate MRI of the spine and initiation of high-dose intravenous corticosteroid therapy. Definitive treatment should include radiation therapy, surgical decompression, or both.
- Zoledronic acid and denosumab are both reasonable treatment options for the prevention of skeletal-related events in patients with castration-resistant bone metastases. Denosumab may include the advantage of not requiring renal dosing. Both agents can (rarely) cause ONJ.
- Radium-223 is a novel alpha-emitting radiopharmaceutical that the FDA has approved for the treatment of symptomatic bone metastases in CRPC patients without visceral metastases or bulky lymph node disease. The recommended dose is 50 kBq/kg intravenously every 4 weeks for a total of 6 cycles.

most commonly the lung. Among these are the expression of receptors to various neuroendocrine peptide growth factors, such as somatostatin, chromogranin A, and serotonin, as well as PTHrP and TP53 mutations. These tumors have an uncharacteristic clinical behavior (compared to the usual metastatic prostate cancer), reflected by frequent visceral involvement and rapidly growing soft-tissue metastases. Patients frequently present with subacute and often dramatic changes in their disease pattern characterized primarily by a rapidly growing soft-tissue mass (frequently involving the primary site but also with retroperitoneal masses), rapid development of visceral (especially liver) infiltration, osteolytic (as opposed to osteoblastic) bone metastasis, and a high incidence of parenchymal brain involvement (Fig. 121-9). Histologic evaluation is strongly encouraged. This frequently culminates with the demonstration of a small cell variant or a poorly differentiated neoplasm

on pathology with the presence of neuroendocrine markers on immunostaining (diSant'Agnese, 1995; Nelson et al, 2007). Interestingly, patients with this tumor phenotype either stop expressing PSA in the presence of major tumor progression or even have undetectable PSA levels at the time of this transformation.

Treatment of the neuroendocrine/anaplastic phenotype is often similar to that of patients with other neuroendocrine tumors (e.g., small cell carcinoma of the lung) and usually includes combinations of cisplatin and etoposide (Frank et al, 1995), or the combination of docetaxel plus carboplatin (Aparicio et al, 2013). One group has also reported doxorubicin-containing combinations as modestly efficacious (Papandreou et al, 2002). Radiation therapy is effective and should be considered in cases with bulky disease, with brain metastasis, or when local disease control in critical areas may have a positive impact on quality of life (pain, potential pathologic fractures, and bladder outlet obstruction). A combined chemotherapy and radiation therapy approach is frequently necessary to accomplish maximal disease control. Despite high initial response rates with chemotherapy and radiation treatment, the prognosis of these patients remains poor and is dependent on various factors, including extent and location of metastases. In general, survival is less than 12 months.

KEY POINTS: THE NEUROENDOCRINE/ANAPLASTIC PHENOTYPE

- Rapidly growing disease with the following clinical characteristics should prompt evaluation for the neuroendocrine/anaplastic phenotype: pelvic masses, visceral involvement, osteolytic metastasis with hypercalcemia (associated with high serum PTHrP), and brain metastasis.
- PSA is most commonly undetectable (or levels are low/declining) despite evidence of rapid disease progression. Serum chromogranin A and urine serotonin metabolites might be detected.
- These tumors are invariably unresponsive to hormonal manipulations but are transiently sensitive to radiation therapy and chemotherapy including platinum-etoposide combinations (or platinum-docetaxel combinations).

Clinical Characteristics :

- Rapidly growing soft tissue metastasis (visceral and pelvic masses)
- Relatively low or undetectable serum PSA
- Lytic bone metastasis
- Frequent brain metastasis
- Elevated plasma chromogranin levels
- Hypercalcemia

CONCLUSIONS

With more drugs at our fingertips for the treatment of CRPC than ever before, and an increasing number of novel therapeutic targets being discovered every day, we are still left with several challenges and unanswered questions. First we must determine how these approved and experimental therapies should ideally be sequenced in individual patients with CRPC to maximize the therapeutic benefit. Second, we need to develop strategies to combine these drugs optimally in a rational manner, taking advantage of our understanding of negative feedback loops and alternative pathway activation to overcome resistance to monotherapies. Only prospective trials incorporating biomarker-driven hypotheses will ultimately be able to address these key clinical questions. Thus the collection of tumor biopsy specimens or correlative samples may be essential in identifying novel targets or developing enrichment strategies moving forward. Third, we must design smarter trials with the goal of quickly yet reliably identifying agents that do not hold promise, while enabling those that do to move swiftly to registration studies. Finally we must select our patients more carefully based on clinical or molecular characteristics so as to identify the subset most likely to benefit from a particular therapy. Meanwhile several active agents are currently in phase III development, and some of these therapies are also likely to further expand our therapeutic arsenal in the near future for men with mCRPC.

SECTION A Development and Prenatal Urology

122 Embryology of the Genitourinary Tract

John M. Park, MD

Kidney Development

Bladder and Ureter Development

Genital and Reproductive Tract Development

The study of embryology provides a useful foundation for the understanding of definitive human anatomy and various congenital disease processes. During the past few decades, a torrent of molecular information and novel experimental techniques has revolutionized the field of embryology, and the knowledge base continues to expand at an exponential rate. Elucidation of molecular mechanisms of genital development has stemmed from gene analysis, evaluation of disruptions of normal endocrine pathways, congenital abnormalities, and animal models. From the urologic surgeon's perspective, however, the classic, descriptive aspects of anatomic embryology continue to serve as an important reference point from which various congenital problems are solved clinically. The aim of this chapter is to provide a concise presentation of the essential facts of normal genitourinary system development, clarifying the important anatomic features and supplementing them with updated molecular information. Deliberate efforts have been made to separate the ever-expanding molecular information from that of the descriptive, anatomic embryology to keep the main "story" of genitourinary system development clear and understandable from a surgical point of view (Fig. 122-1). To help with visualization of the key events, various schematic drawings are provided. The goal of this chapter is not to provide potential explanations for every congenital defect that might occur in the genitourinary system but to select pertinent examples highlighting the fundamental concepts and principles.

KIDNEY DEVELOPMENT

Early Events

Mammals develop three kidneys in the course of intrauterine life. The embryonic kidneys are, in order of their appearance, the *pronephros*, the *mesonephros*, and the *metanephros*. The first two kidneys regress in utero, and the third becomes the permanent kidney. **Embryologically, all three kidneys develop from the intermediate mesoderm.** As the notochord and neural tube develop, the mesoderm located on either side of the midline differentiates into three subdivisions: *paraxial (somite)*, *intermediate*, and *lateral mesoderm* (Fig. 122-2). As the embryo undergoes transverse folding, the intermediate mesoderm separates away from the paraxial mesoderm and migrates toward the intraembryonic coelom (the future peritoneum). At this time there is a progressive craniocaudal development of the bilateral longitudinal mesodermal masses, called *nephrogenic cords*. Each cord is seen bulging from the posterior wall of the coelomic cavity, producing the *urogenital ridge*.

Pronephros and Mesonephros

The mammalian *pronephros* is a transitory, nonfunctional kidney, analogous to that of primitive fish. In humans, the first evidence of the pronephros is seen late in the third week, and it completely degenerates by the start of the fifth week. The pronephros develops as five to seven paired segments in the region of the future neck and thorax (Fig. 122-3A). Development of the pronephric tubules starts at the cranial end of the nephrogenic cord and progresses caudally. As each tubule matures it immediately begins to degenerate along with the segment of the nephric duct to which the tubules are attached.

The second kidney, the *mesonephros*, is also transient, but in mammals it serves as an excretory organ for the embryo while the definitive kidney, the *metanephros*, begins its development (Fig. 122-3B and C). There is a gradual transition from the pronephros to the mesonephros at about the 9th and 10th somite levels. Development of the *nephric ducts* (also called the *wolffian ducts*) precedes the development of the mesonephric tubules. The nephric ducts can be seen as a pair of solid longitudinal tissue condensations at about the 24th day, developing parallel to the nephrogenic cords in the dorsolateral aspect of the embryo. Its blind distal ends grow toward the primitive cloaca and soon fuse with it at about the 28th day. As the ducts fuse with the cloaca they begin to form a lumen at the caudal end. This process of canalization then progresses cranially in a reverse direction, transforming the solid tissue condensations into the definitive nephric ducts with excretory capability. Soon after the appearance of the nephric ducts during the 4th week, mesonephric vesicles begin to form. Initially, several spheric masses of cells are found along the medial side of the nephrogenic cords at the cranial end. This differentiation progresses caudally and results in the formation of 40 to 42 pairs of mesonephric tubules, but only about 30 pairs are seen at any one time because the cranially located tubules start to degenerate starting at about the 5th week. By the 4th month, the human mesonephros has almost completely disappeared, except for a few elements that persist into maturity as part of the reproductive tract. **In males, some of the cranially located mesonephric tubules become the efferent ductules of the testes. The epididymis and vas deferens are also formed from the nephric (wolffian) ducts. In females, remnants of cranial and caudal mesonephric tubules form small, nonfunctional mesosalpingeal structures termed the *epoöphoron* and *paroöphoron*.**

The mesonephric tubules differentiate into excretory units that resemble an abbreviated version of an adult nephron. Shortly after the cell clusters are formed they develop lumens and take the shape

A. Kidney development

B. Ureter and bladder development

Figure 122-1. A to C, Timeline and overview of genitourinary system development. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Figure 122-2. The intermediate mesoderm gives rise to paired, segmentally organized nephrotomes from cervical to sacral region. Cervical nephrotomes are formed early during the fourth week and are collectively referred to as the *pronephros*. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

of vesicles. As the vesicle elongates, each end curves in an opposite direction to form an S-shaped tubule. The lateral end forms a bud that connects with the nephric duct. The medial end lengthens and enlarges to form a cup-shaped sac, which eventually wraps around a knot of glomerular capillaries to form a renal corpuscle. The tuft of glomerular capillaries originating from a branch of the dorsal aorta invades the developing glomerulus; an efferent arteriole empties into a subcardinal sinus.

Metanephros

The definitive kidney, or the *metanephros*, forms in the sacral region as a pair of new structures, called the *ureteric buds*, sprout from the distal portion of the nephric duct and come in contact with the condensing blastema of *metanephric mesenchyme* at about the 28th day (Fig. 122-4). The ureteric bud penetrates the metanephric mesenchyme and begins to divide dichotomously. The tip of the dividing ureteric bud, called the *ampulla*, interacts with the metanephric mesenchyme to induce formation of future nephrons via mesenchymal-epithelial interaction. As the ureteric bud divides and branches, each new ampulla acquires a caplike condensation of metanephric mesenchyme, thereby giving the metanephros a lobulated appearance (Fig. 122-5).

The ureteric bud and metanephric mesenchyme exert reciprocal inductive effects toward each other, and the proper differentiation of these primordial structures depends on these inductive signals

(see the discussion of [molecular mechanisms of kidney development](#), later). The metanephric mesenchyme induces the ureteric bud to branch and divide, and in turn the ureteric bud induces the metanephric mesenchyme to condense and undergo mesenchymal-epithelial conversion. The **nephron**, which consists of the glomerulus, proximal tubule, loop of Henle, and distal tubule, is thought to derive from the metanephric mesenchyme, while the collecting system, consisting of collecting ducts, calyces, pelvis, and ureter, is formed from the ureteric bud (Fig. 122-6).

In principle, all nephrons are formed in the same way and can be classified into fairly well-defined developmental stages (Larsson et al, 1983) (Fig. 122-7). The metanephric mesenchyme first condenses to form a four- to five-cell layer condensate around the ampulla of the advancing ureteric bud. Near the interface of the ampulla and its adjacent ureteric branch, a cluster of cells separates from the condensate and forms an oval mass, called a *pretubular aggregate*. An internal cavity forms within the pretubular aggregate, at which point the structure is called a *renal vesicle* (stage I). Cells of the stage I renal vesicle are tall and columnar and are stabilized by their attachments to the newly formed basement membrane. It has not yet established a contact with the ampulla of the ureteric bud, but it subsequently forms a luminal connection. Multipotential precursors residing in renal vesicles ultimately give rise to all the epithelial cell types of the nephron (Herzlinger et al, 1992). Nephron segmentation into glomerular and tubular domains is initiated by the sequential formation of two clefts in the renal vesicle (stage II). Creation of a lower cleft, termed the *vascular cleft*, precedes formation of a comma-shaped body. Generation of an upper cleft in the comma-shaped body precedes formation of an S-shaped body. At this stage, the cup-shaped glomerular capsule is recognized in the lowest limb of the S-shaped tubule. Epithelial cells lining the inner wall of this cup will comprise the visceral glomerular epithelium, or podocyte layer. Cells lining the outer wall of the cup will form parietal glomerular epithelium, which lines the Bowman capsule. The glomerular capillary tuft is formed via recruitment and proliferation of endothelial and mesangial cell precursors. The rest of the S-shaped tubule develops into the proximal tubule, the loop of Henle, and the distal tubule. When the cup-shaped glomerular capsule matures into an oval structure, the nephron has now passed into stage III of development. Now the nephron can be divided into identifiable proximal and distal tubules. The stage IV nephron is characterized by a round glomerulus that closely resembles the mature renal corpuscle. The morphology of the proximal tubule resembles that of a mature nephron, whereas the distal segments are still primitive. In some species, such as rodents, all stages of nephron development are present at birth, whereas in others, such as humans, all nephrons at birth are in varying steps of stage IV. Mesenchymal cells that do not become tubular epithelium give rise to interstitial stromal cells, which differentiate into a diverse population including fibroblasts, lymphocyte-like cells, and pericytes. Overall, these events are reiterated throughout the growing kidney so that older, more differentiated nephrons are located in the inner part of the kidney near the juxtamedullary region and newer, less differentiated nephrons are found at the periphery (Fig. 122-8). In humans, although renal maturation continues to take place postnatally, nephrogenesis is completed before birth at around 32 to 34 weeks of gestation.

Collecting System

The dichotomous branching of the ureteric bud determines the eventual pelvicalyceal patterns and their corresponding renal lobules (Cebrian et al, 2004) (Fig. 122-9). In humans, the first nine branch generations are formed by approximately 15 weeks' gestation. By 20 to 22 weeks, ureteric bud branching is completed. Thereafter, collecting duct development occurs by extension of peripheral branch segments. Between 22 and 24 weeks of human fetal gestation the peripheral (cortical) and central (medullary) domains of the developing kidney are established. The renal cortex, which represents 70% of total kidney volume at birth, becomes

Figure 122-3. Development of pronephros and mesonephros. A, Pronephros develops in each of five to seven cervical segments, but this primitive renal structure degenerates quickly during the fourth week. The (meso)nephric ducts first appear on day 24. B and C, Mesonephric vesicles and tubules form in a craniocaudal direction throughout the thoracic and lumbar regions. The cranial pairs degenerate as caudal pairs develop, and the definitive mesonephros contains about 20 pairs confined to the first three lumbar segments. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Figure 122-4. Metanephric mesenchyme condenses from the intermediate mesoderm during the early part of the fifth week and comes into contact with the ureteric bud, an outgrowth of the nephric duct, while the cranial mesonephros continues to degenerate. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

organized as a relatively compact, circumferential rim of tissue surrounding the periphery of the kidney. The renal medulla, which represents 30% of total kidney volume at birth, has a modified cone shape with a broad base contiguous with cortical tissue. The apex of the cone is formed by convergence of collecting ducts in the inner

Figure 122-5. The ureteric bud divides to form enlarged tips, called ampullae, around which the metanephric mesenchyme condenses and begins nephron differentiation. The remaining mesenchymal cells remain stromal and continue to interact with tubular mesenchymal cells and dividing ureteric bud epithelial cells. (From Potter EL. Normal and abnormal development of the kidney. Chicago: Year Book Medical Publishers; 1972.)

medulla and is termed the *papilla*. Distinct morphologic differences emerge between collecting ducts located in the medulla compared with those located in the renal cortex. Medullary collecting ducts are organized into elongated linear arrays that converge centrally in a region devoid of glomeruli. In contrast, collecting ducts located in the renal cortex continue to induce metanephric mesenchyme. The most central segments of the collecting system, formed from the first five generations of ureteric bud branching, undergo

Figure 122-6. Development of the renal collecting ducts and nephrons. The tip of the dividing ureteric bud induces the metanephric mesenchyme (*in pink*) to condense, which then differentiates into a renal vesicle. This vesicle coils into an S-shaped tubule and ultimately forms a Bowman capsule as well as the proximal convoluted tubules, distal convoluted tubules, and loops of Henle. The ureteric bud (*in purple*) contributes to the formation of collecting ducts. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Figure 122-7. Nephron development as seen from a renal cortex of a 3-day-old rat. A, A developing nephron with S-shaped body (II). B, Oval glomeruli (III). C, Nephron now resembles that of mature tubules and glomeruli (IV). D, Mature superficial glomerulus from adult rat kidney. (From Larsson L, Maunsbach AB. The ultrastructural development of the glomerular filtration barrier in the rat kidney: a morphometric analysis. *J Ultrastruct Res* 1980;72:392.)

Figure 122-8. Schematic representation of progressive nephron differentiation. Older, more differentiated nephrons are located in the inner part of the kidney near the juxtamedullary region; newer, less differentiated nephrons are found at the periphery. (From Potter EL. Normal and abnormal development of the kidney. Chicago: Year Book Medical Publishers; 1972.)

Figure 122-9. Dichotomous branching of the ureteric bud and subsequent fusion of the ampullae to form the renal pelvis and calyces. Circles indicate possible sites of infundibular development among the third, fourth, or fifth generations of branches and their subsequent expansions to give rise to the calyces. (From Potter EL. Normal and abnormal development of the kidney. Chicago: Year Book Medical Publishers; 1972.)

Figure 122-10. Normal and abnormal ascent of the kidneys. A and B, The metanephros normally ascends from the sacral region to its definitive lumbar location between the sixth and ninth weeks. C, Rarely, a kidney may fail to ascend, resulting in a pelvic kidney. D, If the inferior poles of the kidneys fuse before ascent, the resulting horseshoe kidney does not ascend to a normal position owing to entrapment by the inferior mesenteric artery. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

remodeling by increased growth and dilatation of these tubules to form the pelvis and calyces.

Renal Ascent

Between the sixth and ninth weeks the kidneys ascend to a lumbar site just below the adrenal glands (Fig. 122-10). The precise mechanism responsible for renal ascent is not known, but it is speculated that the differential growth of the lumbar and sacral regions of the embryo plays a major role. As the kidneys migrate they are

vascularized by a succession of transient aortic sprouts that arise at progressively higher levels. These arteries do not elongate to follow the ascending kidneys but instead degenerate and are replaced by successive new arteries. The final pair of arteries forms in the upper lumbar region and becomes the definitive renal arteries. Occasionally, a more inferior pair of arteries persists as accessory lower pole arteries. When the kidney fails to ascend properly, its location becomes ectopic. If its ascent fails completely, it remains as a pelvic kidney. The inferior poles of the kidneys may also fuse, forming a horseshoe kidney that crosses over the ventral side of the aorta.

During ascent the fused lower pole becomes trapped under the inferior mesenteric artery and thus does not reach its normal site. Rarely, the kidney fuses to the contralateral one and ascends to the opposite side, resulting in a cross-fused ectopy.

Molecular Mechanism of Kidney Development

The details of inductive interactions among metanephric mesenchyme, ureteric bud epithelia, and more recently the stroma are becoming clearer and provide insights into the complex regulatory mechanisms underlying renal development. **Formation of renal tubules and the collecting system occurs sequentially and requires dynamic interactions among epithelial, mesenchymal, and stromal cells.** Many of the early events in embryonic kidney development were first elucidated by manipulating lower vertebrate embryos and by using a mammalian in vitro organ culture system. Grobstein's pioneering work in the 1950s led to an organ culture technique (Grobstein, 1956) whereby the metanephric mesenchyme is separated from the ureteric bud during the early part of kidney development and grown in vitro on a filter. An inducer tissue, such as ureter or spinal cord, cultured on the opposite side of the filter then provides the inductive signal (Fig. 122-11). This ingenious experimental approach has established the kidney as a model system for studying the role of epithelial-mesenchymal interaction in organ development. The development of many other organs, including lung, salivary glands, gonads, prostate, and bladder, also require epithelial-mesenchymal

interaction for the controlled differentiation and proliferation of tissues.

Formation of Nephric Ducts

The first recognizable event in renal development may be the formation of nephric ducts within the region of the intermediate mesoderm. The molecular signals responsible for this early event, in which seemingly unorganized mesenchymal cells aggregate to become an epithelial duct, remain essentially unknown, but details are beginning to emerge. The early intermediate mesoderm destined to become nephric ducts is distinguished by expression of the transcription factors LIM1, PAX2, and SIM1, but only LIM1 appears to be absolutely essential for nephric duct formation (Shawlot and Behringer, 1995). PAX2 may be important for maintaining other marker gene expression in the nephric ducts (Torres et al, 1995). Available data suggest a model in which few opposing secreted factors from the surrounding tissues cumulatively restrict LIM1 expression to the intermediate mesoderm. LIM1 then activates PAX2 expression to further orchestrate the formation of nephric ducts.

Ureteric Bud Outgrowth toward Metanephric Mesenchyme

The outgrowth of the ureteric bud from the nephric duct and its invasion into the condensing blastema of metanephric mesenchyme is a crucial initiating event in the development of the adult

A In Vivo Development

B In Vitro Transfilter Assay

Figure 122-11. Schematic representation of in vivo kidney development (A) and an in vitro transfilter organ culture system of Grobstein (B). At an early stage of renal development, the metanephric mesenchyme is separated from the ureteric bud and cultured on a filter. If there is an inducer tissue grown on the opposite side of the filter, such as ureter and spinal cord, the metanephric mesenchyme will continue to differentiate into nephron structures. In the absence of inducer tissue, the metanephric mesenchyme will degenerate via apoptosis. (Modified from Vainio S, Muller U. Inductive tissue interactions, cell signaling, and the control of kidney organogenesis. *Cell* 1997;90:975.)

Figure 122-12. Inductive interactions during early kidney development. Glial cell line-derived neurotrophic factor (GDNF) is secreted from the metanephric mesenchyme and activates the RET receptor tyrosine kinase in the ureteric bud epithelium. The expression and localization of GDNF are positively regulated by *Eya1* and *Pax2* and negatively by *FoxC* transcription factors. The inducibility of nephric ducts to GDNF signaling is restricted by the action of bone morphogenetic protein-4 (BMP4). (Modified from Dressler GR. Tubulogenesis in the developing mammalian kidney. *Trends Cell Biol* 2002;12:390–5.)

kidney (*metanephros*). Many candidate genes have been identified to play a critical role in this process (see <http://golgi.ana.ed.ac.uk/kidhome.html>). In particular, several lines of experimental evidence have revealed a crucial role of the RET-GDNF-GFR α 1 pathway in the ureteric bud outgrowth (Fig. 122-12). Glial cell line-derived neurotrophic factor (GDNF) is a secreted peptide expressed in the metanephric mesenchyme that activates the RET receptor, which is expressed along the nephric duct. GDNF activation of RET requires the glycosylphosphatidylinositol (GPI)-linked protein GFR α 1, which is expressed in both metanephric mesenchyme and nephric duct. Gene knockout mutations in *Ret*, *GDNF* (Moore et al, 1996; Pichel et al, 1996; Sánchez et al, 1996), and *GFR α 1* (Cacalano et al, 1998) inhibit ureteric bud outgrowth. In organ culture systems, recombinant GDNF is sufficient to induce ectopic ureteric bud outgrowth (Sainio et al, 1997) (Fig. 122-13). However, the competence of the nephric duct to respond to GDNF is restricted along the anteroposterior axis. This anteroposterior restriction might be mediated by suppressors of RET signaling within the surrounding tissue, such as bone morphogenetic protein-4 (BMP4). Mice that are deficient for BMP4 show more broadened ureteric buds and/or secondary anterior buds, suggesting that full BMP4 activity is required to limit RET signaling to the caudal aspect adjacent to the developing metanephric mesenchyme (Miyazaki et al, 2000). Similarly, in organ culture, BMP4 can suppress the activity of GDNF to induce ectopic ureteric bud formation

Figure 122-13. A, Stimulation of ectopic ureteric buds by glial cell line-derived neurotrophic factor (GDNF). To determine whether GDNF is sufficient to promote outgrowth of nephric duct epithelial cells, heparin acrylamide beads preadsorbed with recombinant GDNF (asterisk) were placed between two nephric duct organ cultures. The native metanephros (m) is seen anteriorly. GDNF alone induces multiple ectopic ureteric buds in the posterior nephric ducts (arrowheads). B, However, the effect of GDNF is suppressed when BMP4 is also added to the beads (asterisks). Cultures were stained with anti-cytokeratin (green) and anti-Pax2 (red) antibodies. (From Dressler GR. Tubulogenesis in the developing mammalian kidney. *Trends Cell Biol* 2002;12:390–5.)

(Brophy et al, 2001). Proper positioning of the ureteric bud is also controlled by the localized expression of GDNF within the metanephric mesenchyme. Both positive and negative regulators have been described for GDNF localization. Homozygous mutation of a transcription factor *Eya1* causes failure of ureteric bud outgrowth, and its metanephric mesenchyme lacks GDNF expression, suggesting that *Eya1* regulates GDNF expression (Xu et al, 1999). In humans, haploinsufficiency of *Eya1* results in a dominantly inherited disorder called *branchio-oto-renal syndrome*, which involves kidney and urinary tract anomalies (Abdelhak et al, 1997). Expression of PAX2 in the metanephric mesenchyme is also required for GDNF activation (Brophy et al, 2001). GDNF expression is also suppressed at the anterior boundary of the metanephric mesenchyme through the concerted action of the *FoxC1* and *FoxC2* transcription factors (Kume et al, 2000). Mutations in either *Fox* gene result in an expansion of GDNF expression and the formation of ectopic ureteric buds. Most *FoxC1* homozygous mutants have duplex kidneys, in which the upper ureter is dilated and connects aberrantly to ectopic nephric duct derivatives in males such as seminal vesicles and vas deferens. In the developing kidneys, *Slit2* is primarily expressed in the nephric duct, whereas *Robo2* is expressed in the metanephric mesenchyme (Piper et al, 2000). Mice deficient in *Slit2* or *Robo2* exhibit ectopic ureteric bud formation, multiple ureters and hydroureter, and anterior expansion of GDNF expression (Grieshammer et al, 2004). *SPRY1* negatively regulates GDNF-RET signaling. Loss of *Spry1* function in mice results in renal malformations, including multiple ureters, duplex kidneys and hydroureter, and increased expression of GDNF in the metanephric mesenchyme (Basson et al, 2006). The data therefore suggest that multiple factors regulate, both positively and negatively, the precise timing and localization of GDNF, which then functions as a guidance cue to activate RET.

Ureteric Bud Branching

Once the ureteric bud has contacted the condensing metanephric mesenchyme it undergoes a dichotomous branching morphogenesis (Cebrian et al, 2004). Many of the same factors that regulate the initial outgrowth of the ureteric bud also appear to be essential for the subsequent branching of the ureteric bud.

Ureteric bud branching is positively regulated by genetic and nutritional factors. PAX2, a paired-box type transcription factor that is mutated in humans with renal coloboma syndrome, is a positive regulator of ureteric bud branching. During renal development, *Pax2* is expressed in the nephric duct, ureteric bud, and metanephric blastema induced by ureteric bud branch tips. Mice with *Pax2* mutation exhibit decreased ureteric bud branching and renal hypoplasia (Porteous et al, 2000). Ureteric branching is also positively regulated by vitamin A and its retinoic acid receptor signaling, which promote Ret expression. *Rar α* and *Rar β 2* are expressed in stromal cells surrounding Ret-expressing ureteric bud branch tips. Mice deficient in these receptors exhibit a decreased number of ureteric bud branches and diminished expression of Ret (Batourina et al, 2001). Certain markers such as Wnt11 might already be compartmentalized to opposing poles of the dilated bud tips, even before a morphologic branch point is evident (Pepicelli et al, 1997). In mice deficient for the homeobox gene *Emx2* (Miyamoto et al, 1997), ureteric bud outgrowth into the metanephric mesenchyme appears normal but the leading edge never dilates and branching is suppressed. Thus ureteric development is arrested before the first branching event, and the resulting metanephric mesenchyme does not express any markers for induction. Similarly, mice with mutation of *Sall1* exhibit developmental arrest just after ureteric bud outgrowth and before dilation of the leading edge (Nishinakamura et al, 2001). In normal murine embryos, *Sall1* is expressed in the metanephric mesenchyme. Thus *Sall1* might control mesenchyme-derived signals that are necessary for ureteric bud dilation and the early branch point determination. Clearly, the pattern of ureteric bud branching and the expression of ureteric bud-specific genes are influenced by the metanephric mesenchyme. Indeed, the heterologous mesenchyme derived from lung primordia can not only change the pattern of ureteric bud branching to that of lung epithelia but also induce the ureteric bud tissues to express lung-specific genes (Lin et al, 2001). Studies have demonstrated that BMP/activin-like kinase-3 (ALK3) signaling negatively regulates early ureteric bud branching in vivo (Hartwig et al, 2008). The cell surface receptor ALK3 binds BMP2 and BMP4 with high affinity and is expressed in the nephric duct. Inactivation of ALK3 changes the pattern of primary ureteric bud branching from bifid to trifid and increases the number of first- and second-generation branches. These defects are associated with decreased formation of subsequent branch generations, resulting in a decreased complement of collecting ducts. These observations suggest that the pattern of early ureteric bud branching is a critical determinant of subsequent branching morphogenesis. Thus ureteric bud epithelial branching morphogenesis is controlled by both intrinsic and extrinsic factors working in concert to generate a kidney-specific branching pattern.

Tubulogenesis

Classic tissue recombination experiments focused almost exclusively on the relationship between metanephric mesenchymal cells and ureteric bud epithelial cells. It is now clear that at least three cell types are involved in the control of renal development: the ureteric bud tip cells, the condensed mesenchymal cells, and the stromal or interstitial mesenchymal cells (Fig. 122-14). It is not known whether the mesenchyme is a homogeneous cell population before its interaction with the ureteric bud. It is clear, however, that once induced by the ureteric bud the metanephric mesenchyme patterns itself into at least two different cell populations, a tubular one and a stromal one. The tubular cell population is thought to derive from mesenchymal cells in direct contact with the ureteric bud ampulla (Vainio et al, 1989; Stark et al, 1994; Torres et al, 1995), whereas the stromal cell population surrounds the tubular cells (Hatini et al, 1996). Once the mesenchyme has been patterned, the cells in the tubular zone undergo morphogenesis to become renal tubular epithelial cells. There is evidence that this process is dependent not only on signals from the ureteric bud but also on signals from the mesenchyme itself. One of these autocrine signals may be Wnt4, whose expression is induced in cells of the

Figure 122-14. Cell-cell interactions promote nephrogenesis. Three major cell types—ureteric bud (UB) epithelial cells, condensing tubular mesenchymal cells, and stromal mesenchymal cells—are thought to play a critical role. At the UB tips, cells express unique markers such as *Emx2* and *Pax2*. The stromal cell lineage is marked by expression of retinoic acid receptors (RAR) and BF2. Presence of *Pax2*, *Wnt1*, and *Sall1* appears to be important for continued branching morphogenesis of the UB. *Wnt4* is activated in the tubular mesenchymal cells by the invading UB epithelial cells and stimulates the development of polarized epithelium in an autocrine fashion. Finally, fibroblast growth factors (FGFs), such as FGF2, along with leukocyte-inhibitory factor (LIF), may be critical as survival factors for the developing renal tubular epithelial cells. (Modified from Dressler GR. Tubulogenesis in the developing mammalian kidney. *Trends Cell Biol* 2002;12:390–5.)

tubular zone on interaction with the ureteric bud. In *Wnt4* gene knockout mice the ureteric bud forms and invades the metanephric mesenchyme, but subsequent development of epithelial tubules is abolished (Stark et al, 1994). This suggests that two signals are essential for renal tubule formation—initial ureteric bud-derived signals activating *Wnt4* expression in the metanephric mesenchyme and *Wnt4* itself as a mesenchymal autocrine signal. Signals from the stromal cell population also contribute to tubule formation, because tubulogenesis is perturbed in *Bf2* gene knockout mice (Hatini et al, 1996). The discovery that *Wnt4* acts as a downstream signal during the induction cascade leading to renal tubulogenesis leads to the question regarding the nature of the initial ureteric bud-derived signals. In vitro data suggest a role for fibroblast growth factor-2 (FGF2) and other uncharacterized factors secreted by the ureteric bud (Karavanova et al, 1996). Candidate molecules that may cooperate with FGF2 are *Wnt11* and *BMP7* (Kispert et al, 1996; Vukicevic et al, 1996). Localization of RET protein to the ureteric bud tips is reinforced by both GDNF (Pepicelli et al, 1997) and signals emanating from surrounding stromal cells. For example, retinoic acid receptors are expressed in the stromal cells and are required for stromal cell-mediated signaling to maintain high levels of RET expression in the bud tips (Mendelsohn et al, 1999; Batourina et al, 2001). Consistent with the role of retinoic acid receptors in maintaining RET expression in the dividing ureteric

bud, rats with vitamin A deficiency have smaller kidneys and fewer nephrons (Lelièvre-Pégurier et al, 1999). The cellular crosstalk among stromal, mesenchymal, and ureteric bud cells is further highlighted by gain- and loss-of-function experiments involving FGFs and BMPs. *Fgf7* null mutant mice have fewer branch points and correspondingly fewer nephrons, whereas ectopic FGF7 in organ culture can stimulate branching (Qiao et al, 1999). FGF1 and FGF10 affect elongation of the ureteric bud stalk before the branch-point decision is made (Qiao et al, 2001). Null mutations in *Bmp7* are associated with even more severe phenotypic anomalies, exhibiting limited branching morphogenesis and complete renal developmental arrest. Yet it is difficult to assess how FGFs and BMPs exert their collective effects on branching given the interplay among all the cell types present in the early kidney (Dudley et al, 1999). In addition to the proteins just mentioned, a growing list of growth factors, secreted peptides, and their receptors have been implicated in the control of branching morphogenesis, most by using a variety of in vitro model systems (Pohl et al, 2000; Davies, 2001). For many of these factors, however, genetic studies have not proved conclusive in assigning specific functional roles during ureteric bud branching in vivo, either because of potential redundancies or embryonic lethalties before the onset of kidney development. Nevertheless, the role of these factors in the renal development must be considered.

Mesenchymal-Epithelial Conversion

The inductive signals emanating from the ureteric bud promote condensation of the metanephric mesenchymal cells around the ureteric bud tips and subsequent tubulogenesis. Mice with null mutations of *Pax2* or *Wt1* fail to exhibit ureteric bud outgrowth, and in both cases the metanephric mesenchyme does not respond to induction even when recombined with strong inducers in vitro (Kreidberg et al, 1993; Brophy et al, 2001). The establishment of glomerular versus tubular cell fates is dependent on negative feedback between *Wt1* and *Pax2* (Ryan et al, 1995). During early kidney development, the expression domain of *Pax2* is complementary to that of *Wt1* in S-shaped bodies. *Wt1* expression is restricted to glomerular epithelial precursors (Pelletier et al, 1991), whereas *Pax2* expression is restricted to the portion that gives rise to tubular epithelial precursors of the proximal and distal nephron segments and later repressed in differentiated tubular epithelium (Dressler and Douglass, 1992). Evidence in support of Wnt proteins as mesenchyme inducers has been gained from in vitro induction assays using Wnt-expressing cell lines (Herzlinger et al, 1994; Kispert et al, 1998). Of the *Wnt* mutants examined to date, only *Wnt4*, which is expressed in the mesenchyme and not the ureteric bud, is crucial for propagation of the inductive signals. Although *Wnt4* mutant mesenchyme is able to aggregate in response to ureteric bud contact, these mutant aggregates do not form polarized epithelia. Rat ureteric bud cells secrete tubulogenic factors, such as leukocyte-inhibitory factor (LIF), which, together with FGF2, appears to stimulate growth and tubulogenesis in vitro (Plisov et al, 2001). Once induced to form aggregates, metanephric mesenchyme becomes polarized into an early renal vesicle. This vesicle is closely associated with the branching ureteric bud and will eventually connect to the ureteric bud epithelium to form a continuous tubule. Profound changes take place in the expression of cell adhesion molecules such as cadherins. Shortly after induction, metanephric mesenchyme expresses R-cadherin, cadherin-6, and E-cadherin, along with suppression of the mesenchyme-specific cadherin-11. Both R-cadherin and cadherin-6 mutants show defects in the rate of mesenchymal condensation and polarization (Mah et al, 2000; Dahl et al, 2002). Some renal vesicles in cadherin-6 mutants also fail to fuse to the ureteric bud epithelia, resulting in “dead end” tubules and a subsequent loss of nephrons.

Renal Vascular Development

The origin of intrarenal vasculature is not completely understood. Until recently it was thought that renal vasculature derived exclu-

sively from branches off the aorta and other preexisting extrarenal vessels (“angiogenic” hypothesis). There is evidence, however, that the renal vessels may originate in situ, within the embryonic kidney from vascular progenitor cells (“vasculogenic” hypothesis) (Loughna et al, 1996; Tufo et al, 1999). Using antibodies to Flk-1, a vascular endothelial growth factor (VEGF) receptor present in angioblasts and mature endothelial cells, it was demonstrated that endothelial cell precursors were already present in the prevascular rodent kidneys before any vessels were discernible from a morphologic standpoint. When embryonic kidneys are cultured at the usual atmospheric oxygen concentration, vessels do not develop. However, if the explants are cultured in a hypoxic atmosphere containing 5% oxygen, capillary sprouts develop within and outside the glomeruli, an effect that is inhibited by anti-VEGF antibodies (Tufo-McReddie et al, 1997). Depending on the developmental potential of the cells involved, both angiogenesis and vasculogenesis may play a role in the development of renal vasculature (Abrahamson et al, 1998).

BLADDER AND URETER DEVELOPMENT

Formation of Urogenital Sinus

At the third week of gestation the cloacal membrane remains a bilaminar structure composed of endoderm and ectoderm. During the fourth week the neural tube and the tail of the embryo grow dorsally and caudally, projecting over the cloacal membrane, and this differential growth of the body results in embryo folding. The cloacal membrane is now turned to the ventral aspect of the embryo, and the terminal portion of the endoderm-lined yolk sac dilates and becomes the *cloaca* (Fig. 122-15). According to the theories of Rathke and Tournoux regarding embryonic development, the partition of the cloaca into an anterior urogenital sinus and a posterior anorectal canal occurs by the midline fusion of two lateral ridges of the cloacal wall and by a descending urorectal septum. This process is thought to occur during the fifth and sixth weeks, and it culminates with the fusion of this urorectal septum with the cloacal membrane. However, some investigators have challenged this classic view with evidence that there is neither a descending septum nor fusing lateral ridges of the cloacal wall (van der Putte, 1986; Kluth et al, 1995). There is further evidence that the urorectal septum never fuses with the cloacal membrane (Nievelstein et al, 1998). According to these observations the congenital cloacal and anorectal malformations, which were previously thought to occur because of a failure of septum formation and its fusion with the cloacal membrane, may in fact occur from an abnormal development of the cloacal membrane itself (Nievelstein et al, 1998) (Fig. 122-16).

The nephric (wolffian) duct fuses with the cloaca by the 24th day and remains with the urogenital sinus during the cloacal separation. The entrance of the nephric duct into the primitive urogenital sinus serves as a landmark distinguishing the cephalad vesicourethral canal from the caudal urogenital sinus. The vesicourethral canal gives rise to the bladder and pelvic urethra, whereas the caudal urogenital sinus forms the phallic urethra for males and distal vaginal vestibule for females.

Formation of Trigone

By day 33 of gestation, the *common excretory ducts* (the portion of nephric ducts distal to the origin of ureteric buds) dilate and connect to the urogenital sinus. The formation of these final connections involves apoptosis, which enables the ureters to disconnect from the nephric ducts, and fusion, in which the ureteral orifice inserts into the urogenital sinus epithelium at the level of the trigone (Batourina et al, 2005). According to the classic view (Weiss, 1988), the right and left common excretory ducts fuse in the midline as a triangular area, forming the primitive trigone, structurally different from bladder and urethra. The ureteral orifice extrophies and evaginates into the bladder by day 37 and begins to migrate in a cranial and lateral direction within the floor of the bladder. During this process the nephric duct orifice diverges

Figure 122-15. Development of the urogenital sinus. Between the fourth and sixth weeks the cloaca is divided into an anterior urogenital sinus and a posterior anorectal canal. The superior part of the urogenital sinus, continuous with the allantois, forms the bladder. The constricted narrowing at the base of the urogenital sinus forms the pelvic urethra. The distal expansion of the urogenital sinus forms the vestibule of the vagina in females and the penile urethra in males. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

away from the ureteral orifice and migrates caudally, flanking the paramesonephric (müllerian) duct at the level of the urogenital sinus. This is the site of the future verumontanum in males and vaginal canal in females. Studies, however, have challenged this classic mechanism of trigone development. With use of the cell lineage studies in mice, the trigone was found to form mostly from bladder smooth muscle cells with only a minor contribution from the ureters (Viana et al, 2007).

The embryonic pattern of ureteral orifice incorporation into the developing bladder is inferred primarily from clinical observations of duplex kidneys. The upper pole ureteral orifice rotates posteriorly relative to the lower pole orifice and assumes a more caudal and medial position. Weigert and Meyer recognized the regularity of this relationship between upper and lower pole ureteral orifices, which has come to be known as the *Weigert-Meyer rule*. According to this

concept, an abnormally lateral lower pole ureteral orifice may result from a ureteric bud arising too low on the nephric duct, therefore resulting in premature incorporation and migration within the developing bladder. In such a ureteral orifice, vesico-ureteral reflux is more likely to occur because of an inadequate intramural tunnel. In contrast, an abnormally caudal upper pole ureteral orifice may result from a ureteric bud arising too high on the nephric duct. It may drain at the bladder neck and verumontanum or remain connected to the nephric (wolffian) duct derivatives such as the vas deferens in males (Mackie and Stephens, 1977; Schwarz and Stephens, 1978). In females, the ectopic upper pole ureter may insert into the remnants of the nephric ducts (e.g., Gartner duct cyst) or vaginal vestibule (Fig. 122-17).

Anomalous development of the common excretory duct may lead to an ectopic vas deferens. In certain clinical situations the vas deferens is connected to the ureter rather than the verumontanum, so that both the ureter and vas drain into a common duct. This situation may occur when the ureteric bud arises too high on the nephric duct and the subsequent common excretory duct becomes too long, resulting in incomplete absorption into the developing bladder. This anomaly, although rare, should be kept in mind when evaluating males with recurrent epididymitis and ipsilateral hydronephrosis.

Development of the Ureter

In contrast to the previous discussion regarding the molecular aspects of renal development, little is understood at the molecular level concerning the events of ureteral development. Only a small amount of descriptive information and a few speculative theories are available regarding the molecular mechanism of smooth muscle cell and urothelial differentiation. Morphologically, the ureter begins as a simple cuboidal epithelial tube surrounded by loose mesenchymal cells that acquires a complete lumen at 28 days of gestation in humans. It was suggested that the developing ureter undergoes a transient luminal obstruction between 37 and 40 days' gestation and subsequently recanalizes (Alcaraz et al, 1991). It appears that this recanalization process begins in the mid-ureter and extends in a bidirectional manner both cranially and caudally. In addition, another source of physiologic ureteral obstruction may exist as the Chwalla membrane, a two-cell-thick layer over the ureteral orifice that is seen between 37 and 39 days' gestation. In humans, urine production is followed by proliferative changes in the ureteral epithelium (bilaminar by 10 weeks of gestation). The epithelium attains a transitional configuration by 14 weeks. The first signs of ureteral muscularization and development of elastic fibers are seen at 12 weeks of gestation. In both rats and humans the ureteral smooth muscle phenotype appears later than that of the bladder. Smooth muscle differentiation is first detected in the subserosal region of the bladder dome and extends toward the bladder base and urethra, whereas smooth muscle differentiation of the ureter occurs later within the subepithelial region in the ureterovesical junction, ascending toward the intrarenal collecting system (Baker and Gomez, 1998). In the embryonic ureter and bladder it is likely that epithelial-mesenchymal interactions are important in the development of urothelium, lamina propria, and muscular compartments, but the exact nature of this induction process is unknown. Before 10 weeks of gestation elastic fibers are few in number, poorly developed, and randomly arranged. After 12 weeks these fibers become more numerous throughout the ureter and are seen with specific orientation (Escala et al, 1989).

Although more than 30 genes have been found to be involved in the development of mammalian kidneys, only a few genes have been thus far demonstrated to concurrently cause both kidney and ureteral anomalies—*Agtr2*, *Bmp4*, *FoxC1*, *Pax2*, and *Eya1* (see the discussion of molecular mechanism of kidney development, earlier). A mutation of the *PAX2* gene has been identified in a human family carrying renal coloboma syndrome, a rare autosomal dominant syndrome characterized by optic nerve coloboma, renal anomalies, and vesicoureteral reflux (Sanyanusin et al, 1996). *EYA1* is mutated in patients with dominantly inherited disorder,

Figure 122-16. Abnormal development of cloacal membrane results in characteristic anomalies of the urogenital and lower gastrointestinal tract. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Figure 122-17. Development of an ectopic upper pole ureter draining into the vagina. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

branchio-oto-renal syndrome, which includes a duplex collecting system, renal hypoplasia and dysplasia, and renal agenesis (Abdelhak et al, 1997). *Pax2* is required for the growth and elongation of nephric ducts before ureteric bud formation, whereas *Eya1* appears to regulate the GDNF expression, which is a prerequisite for ureteric bud outgrowth. *Bmp4* and *FoxC1* appear to play a suppressive role in the ureteric bud outgrowth.

The renin-angiotensin system is present and active during fetal life. It is generally thought that the major role of this system in the fetus is to maintain fetal glomerular filtration and to ensure adequate urine production (Lumbers, 1995). There is growing evidence, however, that the renin-angiotensin system is also important for normal growth and development of the kidney and ureter. The kidney is able to produce all components of this system, and thus the local (intrarenal) production of angiotensin II may play a critical role in this regard. Renin messenger (m)RNA is detectable in the human mesonephros at about 30 days of gestation and in the metanephros at about 56 days of gestation (Schütz et al, 1996). A similar profile of expression is seen for angiotensinogen and angiotensin-converting enzyme (ACE). Mutant mice lacking ACE are found to have abnormal renal vasculature and tubules as well as increased renin synthesis in interstitial and perivascular cells (Hilgers et al, 1997). Pharmacologic inhibition of ACE in the neonatal rat produces irreversible abnormalities in renal function and morphology (Guron et al, 1997), supporting that an intact renin-angiotensin system is crucial for normal kidney development and maturation. In addition to the high rate of fetal loss, infants born to human mothers treated with ACE inhibitors during pregnancy have increased rates of oligohydramnios, hypotension, and anuria (Shotan et al, 1994; Sedman et al, 1995).

Both subtypes of angiotensin II receptors, AT1 and AT2, are expressed in the developing mesonephros and metanephros. AT2 expression predominates in the undifferentiated mesenchymal cells that surround the nephric duct at the time of ureteric bud outgrowth and declines with maturation, and this pattern of expression suggests AT2's role in embryonic renal development. AT1 is expressed in more differentiated structures and may be involved in modulating later stages of renal vascular development and acquisition of classic angiotensin II-mediated effects of vasoconstriction and sodium reabsorption. The function of the AT2 receptor is not defined completely, but when its gene, *Agtr2*, was inactivated genetically in mice these mutants demonstrated a significant incidence of anomalies in the kidney and urinary tract. Abnormal phenotype in these mice mimicked all the key features of human congenital anomalies of the kidney and urinary tract, such as ureteropelvic junction obstruction, hypoplastic kidney, vesicoureteral reflux, megaureter, and duplicated collecting system (Nishimura et al, 1999).

Because of its embryonic expression pattern, it was initially speculated that AT2 might play a role in regulating the initial outgrowth of the ureteric bud. Analysis of whole tissue sections showed that ectopic ureteric budding occurred in *Agtr2*-deficient mutant mice (Oshima et al, 2001). It was thus postulated that similar to *Bmp4*, AT2 might have a role in directing the site of ureteric bud outgrowth through its inhibitory effect. In other words, a defect in this process may lead to an abnormal timing and location of the ureteric bud outgrowth, resulting in congenital ureteral anomalies.

Recent evidence suggests that BMPs control formation of smooth muscle in the proximal ureter and pelvis. *BMP4*, expressed in the caudal mesenchyme cells, induces ureteral morphogenesis including smooth muscle differentiation and urothelial development (Brenner-Anantharam et al, 2007). Consistent with such a role, *Bmp4*- and *Bmp5*-mutant mice display hydronephrosis and hydro-ureter (Miyazaki et al, 2003).

Development of the Bladder and Continence Mechanism

By the 10th week of gestation the bladder is a cylindric tube lined by a single layer of cuboidal cells surrounded by loose connective tissue. The apex tapers as the urachus, which is contiguous with the

allantois. By the 12th week the urachus involutes to become a fibrous cord, which becomes the *median umbilical ligament*. The bladder epithelium consists of bilayered cuboidal cells between the 7th and 12th weeks, and it begins to acquire mature urothelial characteristics between the 13th and 17th weeks. By the 21st week it becomes four to five cell layers thick and demonstrates ultrastructural features similar to the fully differentiated urothelium. Between the 7th and 12th weeks the surrounding connective tissues condense and smooth muscle fibers begin to appear, first at the region of the bladder dome and later proceeding toward the bladder base. Collagen fibers first appear in the lamina propria and then later extend into the deeper wall between the muscle fibers (Newman and Antonakopoulos, 1989).

Bladder compliance is thought to change during development. When studied in whole organ preparation using fetal sheep bladders, bladder compliance is very low during early gestation and increases gradually thereafter (Coplen et al, 1994). The mechanism of these changes in bladder compliance is not known but may involve alterations in both smooth muscle tone and connective tissue composition. This phenomenon is also observed in developing human bladders (Kim et al, 1991). During gestation the bladder wall muscle thickness increases and the relative collagen content decreases. The ratio of thick-to-thin collagen fibers also decreases, whereas the amount of elastic fibers increases. These changes in compliance seem to coincide with the time of fetal urine production, suggesting a possible role for mechanical distention (Baskin et al, 1994). With fetal mouse bladders used as organ culture explants, bladder distention promoted a more orderly development of collagen fiber bundles within the lamina propria in comparison with decompressed bladder explants, suggesting that mechanical factors from accumulating urine may play a role during bladder development (Beauboeuf et al, 1998).

Similar to other organ development, the epithelial-mesenchymal inductive interactions appear to be necessary for orderly differentiation and proper development of the bladder. A modified Grobstein technique was applied to study the mechanism of bladder smooth muscle cell differentiation (Baskin et al, 1996). Undifferentiated rat bladder epithelial and mesenchymal rudiments were separated before bladder smooth muscle cell differentiation and then recombined to grow within the immunologically compromised host (athymic nude mouse). In the presence of epithelial cells, the mesenchymal cells differentiated into smooth muscle cells with sequential expression of appropriate smooth muscle markers, whereas in the absence of epithelial cells they involuted with evidence of apoptosis.

No functional study has been done to assess fetal continence mechanisms. Only a handful of ontogenic descriptions are available using human fetal specimens, providing a basis for speculative theories. A mesenchymal condensation forms around the caudal end of the urogenital sinus after the division of the cloaca and the rupture of the cloacal membrane. Striated muscle fibers can be seen clearly by the 15th week. At this time the smooth muscle layer becomes thicker at the level of bladder neck and forms the inner part of the urethral musculature. The urethral sphincter, composed of central smooth muscle fibers and peripheral striated muscle fibers, develops in the anterior wall of the urethra (Bourdelat et al, 1992). Beyond this point, sexual dimorphism develops in conjunction with the formation of the prostate in males and the vagina in females (Tichy, 1989). The urethral sphincter muscle fibers extend to the posterior wall of the urethra. In males these fibers project to the lateral wall of the prostate, whereas in females the muscle fibers attach to the lateral wall of the vagina.

GENITAL AND REPRODUCTIVE TRACT DEVELOPMENT

Formation of Genital Ridges and Paramesonephric Ducts

During the fifth week, primordial germ cells migrate from the yolk sac along the dorsal mesentery to populate the mesenchyme of the posterior body wall near the 10th thoracic level (Fig. 122-18). In

Figure 122-18. A, Site of the primordial germ cell origin in the wall of the yolk sac in a 3-week-old embryo. B, Migratory path of the primordial germ cells along the wall of the yolk sac and dorsal mesentery into the developing genital ridges. (Modified from Sadler TW. *Langman's medical embryology*. Baltimore: Williams & Wilkins; 1985.)

both sexes the arrival of primordial germ cells in the area of future gonads serves as the signal for the existing cells of the mesonephros and the adjacent coelomic epithelium to proliferate and form a pair of *genital ridges* just medial to the developing mesonephros (Fig. 122-19). During the sixth week the cells of the genital ridge invade the mesenchyme in the region of future gonads to form aggregates of supporting cells called the *primitive sex cords*. The primitive sex cords will subsequently invest the germ cells and support their development. The genital ridge mesenchyme containing the primitive sex cords is divided into the cortical and medullary regions. Both regions develop in all embryos, but after the sixth week they pursue different fates in the male and female.

During this time a new pair of ducts, called the *paramesonephric (müllerian) ducts*, begins to form just lateral to the nephric ducts in both male and female embryos (Fig. 122-20). These ducts arise by the craniocaudal invagination of thickened coelomic epithelium, extending all the way from the third thoracic segment to the posterior wall of the developing urogenital sinus. The caudal tips of the paramesonephric ducts adhere to each other as they connect with the urogenital sinus between the openings of the right and left nephric ducts. The cranial ends of the paramesonephric ducts form funnel-shaped openings into the coelomic cavity, which is the future peritoneum.

Development of Male Genital Structures

Under the influence of *SRY* (the sex-determining region of the Y chromosome), cells in the medullary region of the *primitive sex cords* begin to differentiate into *Sertoli cells* while the cells of the cortical sex cords degenerate. Sex cord cells differentiate into Sertoli cells only if they contain the *SRY* protein; otherwise the sex cords differentiate into ovarian follicles. During the seventh week, the differentiating Sertoli cells organize to form the *testis cords*. At puberty these testis cords associated with germ cells undergo canalization and differentiate into seminiferous tubules. Direct cell-to-cell contact between developing Sertoli cells and primordial germ cells is thought to play a key role in the proper development of male

gametes. This interaction occurs shortly after the arrival of the primordial germ cells in the presumptive genital ridge. The testis cords distal to the presumptive seminiferous tubules also develop lumen and differentiate into a set of thin-walled ducts called the *rete testis*. Just medial to the developing gonad the tubules of rete testis connect with 5 to 12 residual tubules of nephric ducts, called *efferent ductules*. The vas deferens also develops from the nephric duct. At this time the testis begins to become round, reducing its area of contact with the surrounding mesonephros. As the testis continues to develop, the degenerating cortical sex cords become separated from the coelomic (peritoneal) epithelium by an intervening layer of connective tissue called the *tunica albuginea* (see Fig. 122-20).

As the developing Sertoli cells begin their differentiation in response to the *SRY* protein, they also begin to secrete a glycoprotein hormone called *müllerian-inhibiting substance* (MIS). MIS causes the paramesonephric (müllerian) ducts to regress rapidly between the 8th and 10th weeks. **Small müllerian duct remnants can be detected in the developed male as a small tissue protrusion at the superior pole of the testis, called the *appendix testis*, and as a posterior expansion of the prostatic urethra, called the *prostatic utricle*.** In female embryos, MIS is absent; therefore the müllerian ducts do not regress. On occasion, genetic males have persistent müllerian duct structures (uterus and fallopian tubes), a condition known as *hernia uteri inguinale*. In these individuals either MIS production by Sertoli cells is deficient or the müllerian ducts do not respond to normal MIS levels.

During the 9th and 10th weeks, Leydig cells differentiate from mesenchymal cells of the genital ridge in response to the *SRY* protein. These endocrine cells produce testosterone. At an early stage of development testosterone secretion is regulated by placental chorionic gonadotropin, but eventually the pituitary gonadotropins assume control of androgen production. Between the 8th and 12th weeks, testosterone secretion by Leydig cells stimulates the nephric (wolffian) ducts to transform into the vas deferens. The cranial portions of the nephric ducts degenerate, leaving a small remnant of tissue protrusion called the *appendix epididymis*, and the region of nephric ducts adjacent to the presumptive testis differentiate into

Figure 122-19. Formation of genital ridges and paramesonephric ducts. **A**, During the fifth and sixth weeks the genital ridges form in the posterior abdominal wall just medial to the developing mesonephros. The primordial germ cells induce the coelomic epithelial cells lining the peritoneal cavity and the cells of the mesonephros to proliferate and form the primitive sex cords. **B**, During the sixth week, the paramesonephric ducts develop lateral to the mesonephros. The caudal tips of the paramesonephric ducts fuse with each other as they connect with the urogenital sinus. (Modified from Larsen WJ. *Human embryology*. New York: Churchill Livingstone; 1997.)

the epididymis. During the 9th week, 5 to 12 nephric ducts in the region of the epididymis make contact with the sex cords of the future rete testis. It is not until the third month, however, that these tubules actually establish communication with the rete testis as the efferent ductules. Meanwhile, the nephric duct–derived tubules near the inferior pole of the developing testis degenerate, sometimes leaving a remnant of tissue protrusion called the *paradidymis*.

Prostate and Seminal Vesicle Development

The seminal vesicles sprout from the distal nephric ducts, whereas the prostate and bulbourethral glands develop from the urogenital sinus (Fig. 122-21). They therefore have different

embryologic origins. The initial event in prostatic development is an outgrowth of solid epithelial cords from the urogenital sinus epithelium into the surrounding mesenchyme during weeks 10 to 12 of gestation. This prostatic bud growth and subsequent branching morphogenesis occur in a specific spatial pattern that eventually establishes the lobar subdivisions of the mature prostate gland (Sugimura et al, 1986; Timms et al, 1994). The solid prostatic ducts are subsequently canalized from their urethral connections, proceeding distally toward the ductal tips. As the solid epithelial cords canalize, the epithelium organizes itself into two distinct cell types—luminal and basal cells (Hayward et al, 1996). At this time the prostatic mesenchyme differentiates into a layer of smooth muscle cells that surround the prostatic ducts (Hayward et al, 1996). At puberty, corresponding to a rise in circulating testosterone, the prostate size increases rapidly, along with functional cytodifferentiation of luminal cells, as evidenced by the expression of prostate-specific secretory proteins (Hayward et al, 1996).

Circulating androgens produced by fetal testes play a critical role in the development of the prostate. Cellular responses to circulating androgens are mediated by nuclear androgen receptors that are activated by either testosterone or dihydrotestosterone (DHT). The evidence for the requirement of androgens in establishing the prostate specificity of the urogenital sinus comes primarily from the absence of prostate development in mice and humans who lack functional androgen receptors (Lubahn et al, 1989; He et al, 1991), as well as from the development of the prostate in the female urogenital sinus exposed to androgens (Takeda et al, 1986). In the urogenital sinus, testosterone could activate androgen receptors by directly binding to the receptor and also through a local conversion of circulating testosterone into the more potent DHT by the enzyme 5 α -reductase (Russell and Wilson, 1994). DHT has a 10-fold greater affinity for the androgen receptor than testosterone (Deslypere et al, 1992). When 5 α -reductase is deficient, the urogenital sinus is specified to become the prostate but the overall prostatic growth and development are severely compromised (Andersson et al, 1991). Tissue recombination and grafting experiments using testicular feminization mice that lack functional androgen receptor have shown that the presence of androgen receptors in the urogenital sinus mesenchyme is required for prostate specification and differentiation (Cunha and Lung, 1978). The fact that mesenchymal but not epithelial androgen receptors are required for prostate-specific ductal growth and branching suggests that paracrine signals from the urogenital sinus mesenchyme mediate the action of androgens on the epithelium. Prostate development appears to be affected by the levels of estrogenic compounds as well (vom Saal et al, 1997; Timms et al, 1999), but their specific role has not been fully elucidated.

Prostate development requires inductive and reciprocal interactions between the urogenital sinus epithelium and mesenchyme. In addition to mediating the effect of androgens to the developing prostatic epithelium, paracrine signals from the urogenital sinus mesenchyme also appear to direct lobe-specific patterning of juxtaposed epithelium (Timms et al, 1995). The urogenital sinus mesenchyme, when combined with either embryonic or adult bladder epithelium (also a derivative of endodermal cloaca), will stimulate formation of prostatic ducts. In contrast, the urogenital sinus mesenchyme combined with epithelia of other anatomic origins, such as seminal vesicle (a mesodermal derivative), salivary gland, or esophagus, forms tissues with epithelial characteristics that resemble the anatomic origin of the partnering epithelium (Cunha et al, 1987). These observations suggest that prostate development is spatially restricted by prostate-inducing paracrine signals from the urogenital sinus mesenchyme and that epithelial potential to respond to signals from the urogenital sinus mesenchyme is restricted to the endodermal epithelia of similar embryonic origin as the prostate. The interactions between epithelium and mesenchyme are reciprocal. The presence of prostate epithelium plays a critical role in the differentiation of mesenchymal cells into the periductal smooth muscle cells (Hayward et al, 1998).

Figure 122-20. Male and female gonad and genital development. The male and female genital structures are virtually identical through the seventh week. In males, SRY protein produced by the Sertoli cells causes the medullary sex cords to become presumptive seminiferous tubules and causes the cortical sex cords to regress. Müllerian-inhibiting substance (MIS), a glycoprotein hormone produced by the Sertoli cells, then causes the paramesonephric ducts to regress, leaving behind appendix testis and prostatic utricle as remnants. Appendix epididymis and paradidymis arise from the mesonephric ducts. In females, cortical sex cords invest the primordial germ cells and become the ovarian follicles. In the absence of MIS, the mesonephric ducts degenerate and the paramesonephric ducts give rise to the fallopian tubes, uterus, and upper vagina. The remnants of the mesonephric ducts are found in the ovarian mesentery as the epoöphoron and paroöphoron, and in the anterolateral vaginal wall as the Gartner duct cysts. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Figure 122-21. Development of male accessory sex glands. During the 10th week, the seminal vesicles sprout from the distal mesonephric ducts in response to testosterone whereas the prostate and bulbourethral glands develop from the urethra in response to dihydrotestosterone. Thus the vas deferens and seminal vesicle derive from the mesonephric ducts (MS), and the prostate and bulbourethral glands develop from the urogenital sinus (UG). UB, ureteric bud. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Several candidate genes have been implicated in prostate development, but the nature of paracrine mesenchymal factors that drive urogenital sinus epithelial transformation into prostatic ducts remains unknown. Furthermore, the precise relationship and the embryologic sequence of these candidate molecules have not been clearly defined. The *Hox* family of homeobox genes may be involved in the proper differentiation of male accessory sex glands, including the prostate (Podlasek et al, 1997, 1999b). In particular, *Hoxa-13* and *Hoxd-13* transcription factors are expressed in both urogenital sinus and nephric ducts, and the loss-of-function mutation of these genes in mice results in agenesis of bulbourethral glands and defective morphogenesis of the prostate and seminal vesicles. Two members of the FGF family of secreted proteins, FGF7 and FGF10, are expressed in the urogenital sinus mesenchyme. In vitro organ culture experiments have shown that exogenous FGF7 and FGF10 can stimulate proliferation and branching of developing prostate tissue, but these factors do not appear to be androgen responsive (Thomson and Cunha, 1999). There is also evidence that secreted factor activin-A and its antagonistic binding protein follistatin may be important in the regulation of prostate epithelial development (Cancilla et al, 2001). Activin-A is expressed in both urogenital sinus epithelium and mesenchyme, whereas its receptors are found in the epithelium. Follistatin, an activin-A antagonist, is expressed in the urogenital sinus epithelium. Prostatic ductal growth and branching might therefore be a result of balanced interplay between activin-A and follistatin. Other implicated molecules in prostate development include Bmp4 (Lamm et al, 2001), growth hormone receptor (Ruan et al, 1999), insulin-like growth factor-1 (Ruan et al, 1999), Nkx3.1 (Bhatia-Gaur et al, 1999), sonic hedgehog (Podlasek et al, 1999a), p63 (Signoretti et al, 2000), prolactin (Steger et al, 1998), hyaluronan (Gakunga et al, 1997), fucosyltransferase-1 (Marker et al, 2001), and urokinase plasminogen activator (Elfman et al, 2001).

Development of Female Genital Structures

In female embryos the primitive sex cords do not contain the Y chromosome, do not elaborate SRY protein, and therefore do not differentiate into Sertoli cells. In the absence of Sertoli cells and SRY protein, therefore, MIS synthesis, Leydig cell differentiation,

and androgen production do not occur. Consequently, male development of the genital ducts and accessory glands is not stimulated and female development ensues. In females the primitive sex cords degenerate and the mesothelium of the genital ridge forms the secondary cortical sex cords. These secondary sex cords invest the primordial germ cells to form the ovarian follicles. The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes. The follicle cells then arrest further germ cell development until puberty, at which point individual oocytes resume gametogenesis in response to a monthly surge of gonadotropins.

In the absence of MIS and androgens, the nephric (wolffian) ducts degenerate, and the paramesonephric (müllerian) ducts give rise to the fallopian tubes, uterus, and upper two thirds of the vagina. The remnants of nephric ducts are found in the mesentery of the ovary as the *epoöphoron* and *paroöphoron* and near the vaginal introitus and anterolateral vaginal wall as *Gartner duct cysts*. The distal tips of the paramesonephric ducts adhere to each other just before they contact the posterior wall of the urogenital sinus. The wall of the urogenital sinus at this point forms a small thickening called the *sinusal tubercle*. As soon as the fused tips of the paramesonephric ducts connect with the sinusal tubercle, the paramesonephric ducts begin to fuse in a caudal to cranial direction, forming a tube with a single lumen. This tube, called the *uterovaginal canal*, becomes the superior portion of the vagina and the uterus. The unfused, superior portions of the paramesonephric ducts become the fallopian tubes (oviducts), and the funnel-shaped superior openings of the paramesonephric ducts become the infundibula.

While the uterovaginal canal is forming during the third month, the endodermal tissue of the sinusal tubercle in the posterior urogenital sinus continues to thicken, forming a pair of swellings called the *sinovaginal bulbs*. These structures give rise to the lower third of the vagina. The most inferior portion of the uterovaginal canal becomes occluded transiently by a block of tissue called the *vaginal plate*. The origin of the vaginal plate is not clear; it may arise from the sinovaginal bulbs, from the walls of the paramesonephric ducts, from the nearby mesonephric ducts, or from a combination of these tissues. The vaginal plate elongates between the third to fifth month and subsequently becomes canalized to form the inferior vaginal lumen (Fig. 122-22).

As the vaginal plate forms, the lower end of the vagina lengthens, and its junction with the urogenital sinus migrates caudally until it comes to rest on the posterior wall of definitive urogenital sinus (future vestibule of the vagina) during the fourth month. An endodermal membrane temporarily separates the vaginal lumen from the cavity of the definitive urogenital sinus. This barrier degenerates partially after the fifth month, but its remnant persists as the vaginal hymen. The mucous membrane that lines the vagina and cervix may also derive from the endodermal epithelium of the definitive urogenital sinus.

Development of External Genitalia

Unlike the rest of the developing embryo, the cloacal membrane, along with the oropharyngeal membrane (future oral cavity), is a bilayered structure in which the outer ectoderm remains in close contact with the underlying endoderm without the intervening mesoderm. Initially the cloacal membrane represents an elongated midline structure that extends from the root of the umbilical cord to the future site of the perineum distally. During the subsequent development this bilayered cloacal membrane "retracts" into the perineum as a result of cranial and medial migration of mesodermal cells into the anterior body wall between the ectoderm and the endoderm layers of the cloacal membrane. This mesenchymal migration brings about the closure of the inferior part of the anterior abdominal wall and causes the caudal portion of the cloacal membrane to position itself in the perineal region. These migrating mesodermal cells give rise to the musculature of the medial portion of the anterior abdominal wall, the mesenchymal portion of the anterior bladder wall, the pubic symphysis, and the

Figure 122-22. Development of uterus and vagina. During the 10th week the paramesonephric ducts fuse at their caudal ends to establish a common channel and come into contact with a thickened portion of the posterior urogenital sinus called the sinovaginal bulb. This is followed by development of the vaginal plate, which elongates during the third to fifth months and becomes canalized to form the inferior vaginal lumen. (Modified from Sadler TW. Langman's medical embryology. Baltimore: Williams & Wilkins, 1985.)

rudiments of the external genitalia (Vermeij-Keers et al, 1996). Failure of migration of these mesodermal cells into the midline results in bladder exstrophy and other associated genital defects (Langer, 1993; Vermeij-Keers et al, 1996).

The early development of the external genitalia is similar in both sexes. Migrating mesenchymal cells spread themselves around the cloacal membrane and pile up to form swellings. Early in the fifth week, a pair of swellings called *cloacal folds* develops on either side of the cloacal membrane. These folds meet just anterior to the cloacal membrane to form a midline swelling called the *genital tubercle* (Fig. 122-23). During the cloacal division into the anterior urogenital sinus and the posterior anorectal canal, the portion of the cloacal folds flanking the opening of the urogenital sinus becomes the *urogenital folds* and the portion flanking the opening of the anorectal canal becomes the *anal folds*. A new pair of swellings, called the *labioscrotal folds*, appears on either side of the urogenital folds.

The most popular hypothesis of external genital and urethral development is based on work performed in the early part of the 20th century. Most embryology texts today quote the mechanism of urethral development proposed by Glenister (1954). As the genital tubercle elongates in males, a groove appears on its ventral aspect (called the *urethral groove*) during the sixth week. In both sexes an ectodermal *epithelial tag* is present at the tip of the genital tubercle. The urethral groove is defined laterally by urethral folds, which are continuations of the previous urogenital folds surrounding the urogenital membrane. Initially, the urethral groove extends

Figure 122-23. Early stages of cloacal fold development. (From Hamilton WJ, Mossman HW. Human embryology: prenatal development of form and function. New York: Macmillan; 1976; and Waterman RE. Human embryo and fetus. In: Hafez ESE, Kenemans P, editors. Atlas of human reproduction. Hingham [MA]: Kluwer Boston; 1982.)

only part of the way distally along the shaft of the elongating genital tubercle. The distal portion of the urethral groove terminates in a solid epithelial plate called the *urethral plate* that extends into the glans penis. The solid urethral plate canalizes and thus extends the urethral groove distally toward the glans. The urethral groove is thought to be lined by endoderm. Likewise, the solid urethral plate, the distal precursor of the urethral groove, is also believed to derive from the endodermal source. Clearly, fusion of the urethral folds

is the key step in the formation of penile urethra. A prerequisite of urethral fold fusion is the canalization of solid urethral plate and formation of the urethral groove bounded on each side by the urethral folds. If the urethral groove and urethral fold formations are abnormal, then the urethral fold fusion is likely to be impaired as well (Figs. 122-24 and 122-25).

The formation of the distal glanular urethra may occur by a combination of two separate processes—the fusion of urethral

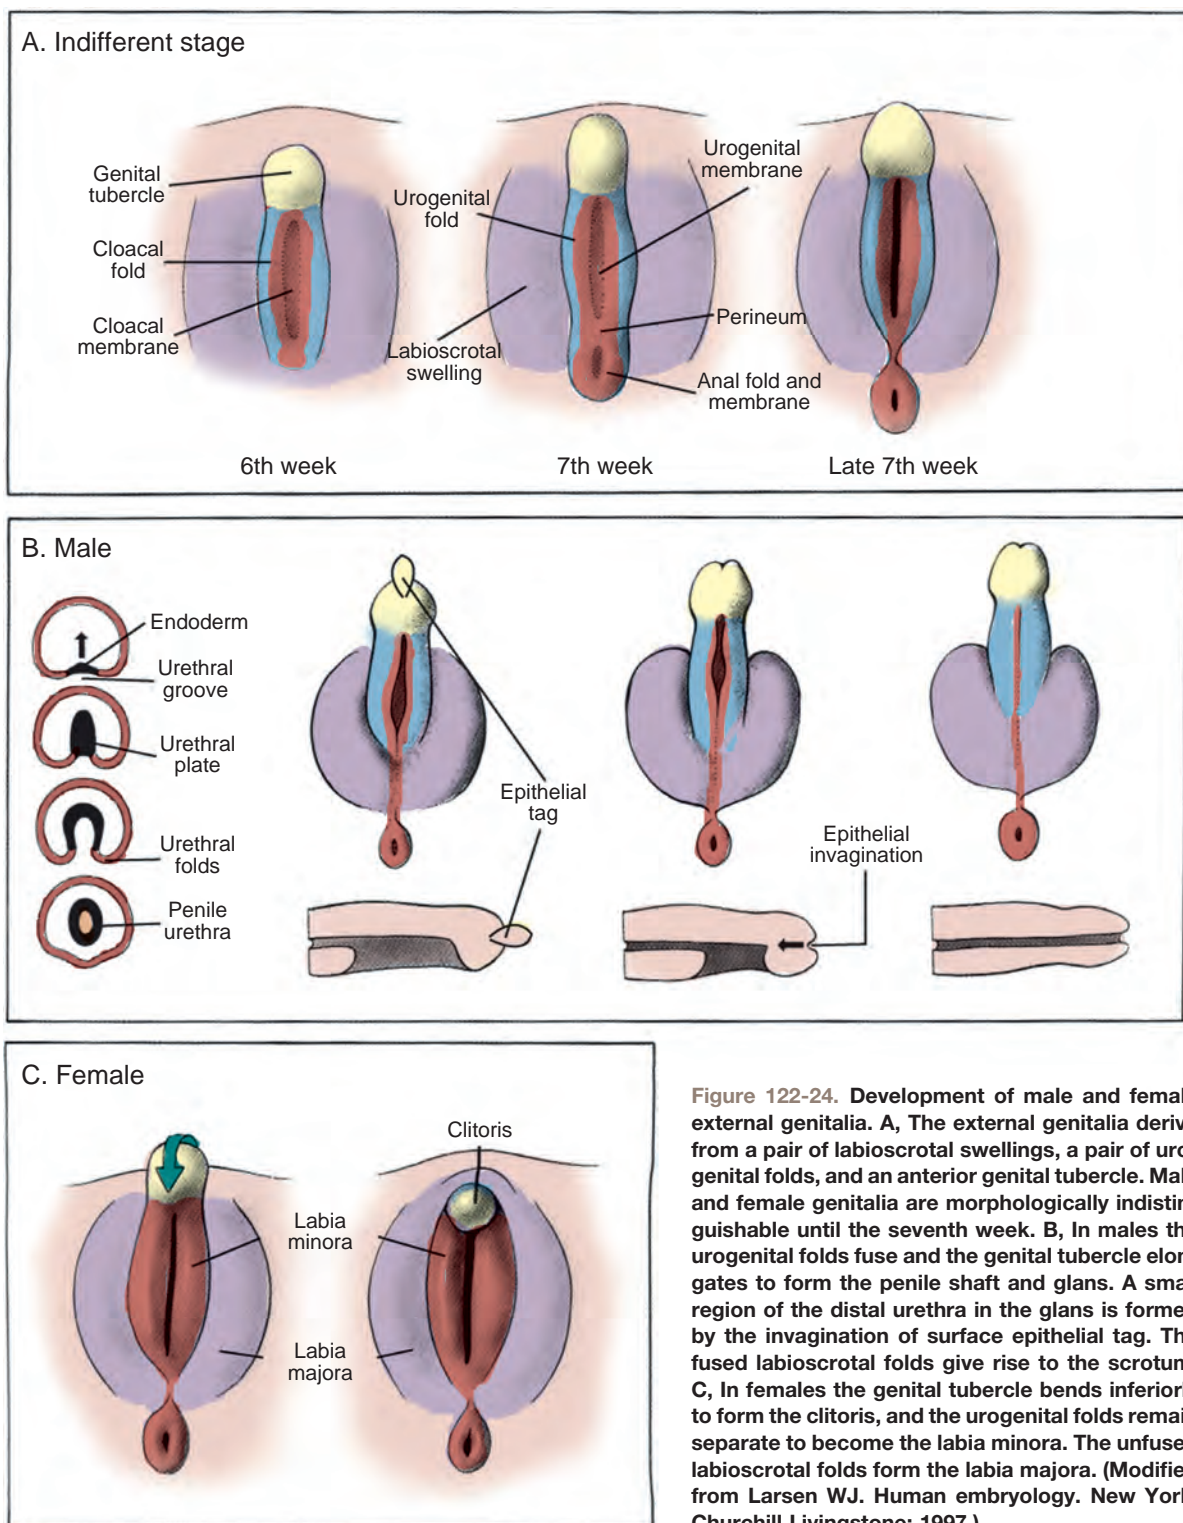

Figure 122-24. Development of male and female external genitalia. A, The external genitalia derive from a pair of labioscrotal swellings, a pair of urogenital folds, and an anterior genital tubercle. Male and female genitalia are morphologically indistinguishable until the seventh week. B, In males the urogenital folds fuse and the genital tubercle elongates to form the penile shaft and glans. A small region of the distal urethra in the glans is formed by the invagination of surface epithelial tag. The fused labioscrotal folds give rise to the scrotum. C, In females the genital tubercle bends inferiorly to form the clitoris, and the urogenital folds remain separate to become the labia minora. The unfused labioscrotal folds form the labia majora. (Modified from Larsen WJ. Human embryology. New York: Churchill Livingstone; 1997.)

Figure 122-25. The epithelial tag (asterisk) and fusing urethral folds (arrows) in the developing male external genitalia. (From Waterman RE. Human embryo and fetus. In: Hafez ESE, Kenemans P, editors. Atlas of human reproduction. Hingham [MA]: Kluwer Boston; 1982.)

folds proximally and the ingrowth of ectodermal cells distally. It is generally thought that the stratified squamous epithelium of the fossa navicularis results from an ingrowth of surface ectoderm as far proximally as the valve of Guérin. The lacuna magna (also known as the sinus of Guérin), which can give symptoms of hematuria and dysuria in some boys, may form as a result of dorsal extension of this ectodermal ingrowth. It was suggested recently that the entire penile urethra might differentiate from the fusion of the endodermal urethral groove via the mechanism of epithelial-mesenchymal interactions (Kurzrock et al, 1999).

Development of external genitalia occurs via three main pathways: (1) androgen independent, (2) androgen dependent, and (3) endocrine and environmental influence. A complex interaction among these three pathways exists, and external genitalia development should be evaluated in the context of all three. Endocrine and environmental influences affect both androgen-independent and androgen-dependent pathways on a genetic and epigenetic basis.

The molecular basis of the sexual dimorphism in genital development is based on the presence or absence of the signaling via the androgen receptor. During embryonic weeks 9 and 10 SRY (sex-determining region of Y chromosome) causes differentiation of Leydig cells, which produce testosterone. In the presence of fetal testicular androgens the wolffian ducts persist and develop into the epididymis, vas deferens, and seminal vesicles. Testosterone is also a substrate for the enzyme, 5α -reductase, which converts testosterone to DHT. This even more potent androgen drives growth of the external genitalia and prostate. The effects of both testosterone and DHT are elicited following interaction of these hormones with the androgen receptor, a nuclear transcription factor. In the absence of functional androgen receptors, the wolffian ducts degenerate, the prostate does not develop from the urogenital sinus, and the external genitalia develop according to the female pattern.

The key role of androgen in sexually dimorphic development of the external genitalia has been corroborated through many experimental studies. In utero exposure of rodents to antiandrogenic compounds reduces the size of the genital tubercle and prevents the development of the scrotum. Likewise, in utero exposure of rats to 5α -reductase inhibitors leads to the development of hypospadias. Mice and humans with functional loss of androgen receptors via mutations demonstrate a complete feminization of the external genitalia.

The elongating phallus is covered externally by ectoderm that gives rise to the penile skin, whereas most of the substance of the penis is derived from mesodermal cells forming the corporeal bodies, connective tissue, and dermis. Corporeal tissue is first recognized as distinct dense mesenchymal condensations within the shaft of the developing penis. Little is known regarding the molecular regulatory mechanisms of the differentiation of penile mesenchyme into its various derivatives, but it is likely that this process is dependent on epithelial-mesenchymal interactions.

In the female, because of the absence of androgen receptor signaling via DHT, the primitive perineum does not lengthen and the labioscrotal and urethral folds do not fuse across the midline. The phallus bends inferiorly, becoming the clitoris, and the ostium of the urogenital membrane becomes the vestibule of the vagina. The urethral folds become the labia minora, and the labioscrotal folds become the labia majora. The external genitalia develop in a similar manner in genetic males who are deficient in 5α -reductase and therefore lack DHT.

Sonic hedgehog (Shh) is a gene that regulates development of two major body appendages, limbs, and the genital tubercle. *Shh* is expressed within the genital tubercle in urethral plate epithelium in mice and has been demonstrated to be involved in formation of the sexually undifferentiated stage and subsequent initiation of sex differentiation of the penis (Miyagawa et al, 2011). *Wnt5a*, β -catenin, and *Fgf8* act downstream of *Shh*, and β -catenin gain-of-function

mutations or exogenous upregulation of β -catenin can rescue genital tubercle development in *Shh*-null mice and recover *Fgf8* expression (Miyagawa et al, 2009a). The *Wnt*/ β -catenin pathway has been demonstrated to be essential in androgen-regulated pathways of genital tubercle development in embryonic mice, and overexpression of β -catenin resulted in masculinization of female mice characterized by prepuce hypertrophy and enlargement of the external genitalia (Miyagawa et al, 2009b). In human embryos, *SHH* is expressed in human fetal penises during development, with the greatest expression demonstrated with immunohistochemistry during urethral tubularization at 14 weeks of gestation (Shehata et al, 2011).

Molecular mechanisms of external genitalia development have been elucidated from understanding the genes involved in congenital syndromes affecting external genitalia. Autosomal dominant mutations in the chromodomain-helicase-DNA-binding protein 7 (*CHD7*) gene result in the CHARGE syndrome (coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies), and a variety of mutations in *CHD7* are found in over 75% of CHARGE syndrome patients (Blake and Prasad, 2006). Genital hypoplasia is more evident in males with CHARGE syndrome and may result in cryptorchidism, micropenis, and/or hypogonadotrophic hypogonadism. The syndrome of Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation (WAGR), which results from chromosomal deletion at 11p13 and affects the *WT1* gene, may result in hypospadias, cryptorchidism, or ambiguous genitalia. Denys-Drash syndrome and Frasier syndrome are both associated with defects in *WT1* and a spectrum of external genitalia abnormalities including ambiguous genitalia, hypospadias, and cryptorchidism (Le Caignec et al, 2007). Defective androgen receptors result in androgen insensitivity syndrome, which has a spectrum of phenotypes depending on the degree of defectiveness of the androgen receptor. A fully nonfunctional androgen receptor will result in an XY individual with phenotypically female external genitalia (Galani et al, 2008). Mutations in the androgen receptor gene are associated with defects in masculinization of the external genitalia and hypospadias, a triad of abnormal urethral, penile, and foreskin development (Wang et al, 2004). Defects in the aromatase gene, which converts testosterone to estrogen, result in elevated testosterone, which causes ambiguous genitalia in 46,XX individuals with virilization of the clitoris to a phallus-like structure (Lin et al, 2007).

Gonadal Descent

Morphologically, the human urogenital ridge is identical in both sexes at 7 to 8 weeks of gestation. Before gonadal differentiation, the testis lies near the developing kidney, loosely held in place by two ligamentous structures. The dorsal ligament is referred to as the *cranial suspensory ligament* (CSL), whereas the ventral ligament later develops into the *gubernaculum* (Fig. 122-26). Between 10 and 15 weeks, the testis remains close to the future inguinal region during the enlargement of the abdominal cavity while the ovary moves more cranially. The testis is anchored near the inguinal region by enlargement of the gubernaculum and regression of the CSL. As early as the 1700s, enlargement of the gubernaculum in males was observed to tether the testis near the groin while the kidney migrated cranially (Wyndham, 1943; van der Schoot, 1993). In females, the CSL continues to develop, keeping the ovary close to the kidney while the gubernaculum involutes. In males, androgen induces resorption of the CSL while the gubernaculum enlarges to become a plump ligamentous body, "holding" the testis close to the inguinal region. Starting in the seventh month, the gubernaculum begins to bulge beyond the external inguinal ring and descends to the scrotal location, while simultaneously it is hollowed out by the evaginating peritoneal diverticulum called the *processus vaginalis* (Heyns, 1987). The processus vaginalis allows the intra-abdominal testis to exit the abdominal cavity. The bulky distal end of the gubernaculum (known as the *bulb*) is resorbed in humans after completion of inguinoscrotal migration.

Figure 122-26. Mechanism of gonadal descent. The undifferentiated gonad is initially located high in the abdomen, anchored by the cranial suspensory ligament (CSL). In males, *InsI3* will cause the swelling and enlargement of the gubernaculum to pull the developing testis toward the inguinal region, whereas androgens will cause an involution of CSL. Owing to the action of müllerian-inhibiting substance, müllerian ducts will regress while androgens continue to stimulate the development of wolffian ducts into male genital ductal structures. In females, CSL persists because of the absence of androgens, and the gubernaculum remains thin as a result of the absence of *InsI3* activity, thereby keeping the ovary well within the pelvis.

Caudal enlargement of the gubernaculum during the early relative transabdominal movement of the testis is known as the "swelling reaction" or "gubernacular outgrowth." The proximal gubernacular cord appears to shorten during this process, as it becomes incorporated into the enlarging bulb (Wensing, 1986). Shortening of the cord may be an important mechanism to position the testis over the inguinal ring to permit abdominal pressure to push the testis out of the abdomen (Quinlan et al, 1988; Attah and Hutson, 1993; Husmann and Levy, 1995). Transection of the gubernacular cord can lead to either accidental testicular descent into the contralateral inguinal canal or aberrant intra-abdominal location (Frey and Rajfer, 1984; Beasley and Hutson, 1988; Attah and Hutson, 1993).

Although intra-abdominal pressure may not be a factor during the initial transabdominal descent, it is thought to be important during transit through the inguinal canal and the subsequent scrotal migration. Inguinoscrotal descent requires migration of the gubernaculum over a considerable distance, along with an increase in the length of the processus vaginalis. The force for movement may come from the intra-abdominal pressure, transmitted directly and indirectly to the testis via the lumen of the processus vaginalis and the gubernacular cord, respectively.

Although patients with defective androgen production or metabolism show varied manifestations of cryptorchidism, the exact role of androgen in testicular descent still remains unclear. During

intra-abdominal testicular descent, androgen appears to play a role in the regression of the CSL (van der Schoot, 1992). Gubernacular enlargement, in contrast, seems to occur independent of androgen activity, because it occurs in androgen-resistant mice and humans normally, being able to keep the testis close to the inguinal region (Hutson, 1985). The second migratory step—the inguinoscrotal phase—is thought to be more androgen dependent. Migration of the gubernaculum beyond the inguinal region is absent in gonadotropin-deficient mice (Grocock et al, 1988) and those with complete androgen resistance (Hutson, 1986). Regression of the gubernacular bulb after the completion of scrotal descent also appears to be androgen dependent because in humans with androgen resistance the gubernaculum remains enlarged (Hutson, 1986).

MIS is a glycoprotein produced and secreted by Sertoli cells and is responsible for regression of the müllerian ducts (Josso et al, 1993; Lee and Donahoe, 1993). Evidence for the role of MIS in testicular descent is conflicting. Some clinical observations support the role of MIS, including patients with persistent müllerian duct syndrome caused by genetic defects of MIS or its receptor gene (Josso et al, 1983). In this clinical scenario the testes are undescended and the gubernaculum is thin and elongated. Transgenic mice with MIS deficiency show a variable testicular position depending on their androgenic status: those with normal androgen receptors have normally descended testes, whereas those with androgen resistance have completely undescended testes (Behringer et al, 1994). A recent study on MIS-receptor knockout mice, however, failed to show any defect in gubernacular development and testicular positions (Bartlett et al, 2002).

INSL3 was identified as a novel gene product of the Leydig cells in 1993 (Adham et al, 1993). INSL3 is similar in structure to the peptide hormones relaxin or insulin and is expressed in both fetal and adult Leydig cells in a differentiation-dependent manner (Balvers et al, 1998). Mice lacking a functional *Insl3* gene demonstrate intra-abdominal cryptorchidism but otherwise no obvious defects in other male reproductive organs. Of more importance, early surgical correction of the cryptorchidism in these mice can restore normal fertility potential (Nef and Parada, 1999; Zimmermann et al, 1999). These are important findings because they reflect the phenotype most commonly observed in classic cryptorchidism in humans. Recently, a G protein–coupled receptor—LGR8—has been cloned with binding and functional response to INSL3 in transfected cells (Hsu et al, 2002; Kumagai et al, 2002). Moreover, mutations in this receptor in mice can lead to the development of cryptorchidism and have been linked to cryptorchidism in humans (Overbeek et al, 2001; Gorlov et al, 2002). Treatment of rat gubernacular explant with exogenous INSL3 leads to a rapid growth of the ligament, an effect that synergizes with androgen treatment (Kubota et al, 2002). It was also demonstrated that LGR8 was expressed in the rat gubernaculum (Kubota et al, 2002). Although INSL3 appears to be a good candidate for a responsible gene for cryptorchidism, to date no causative mutations have been identified in the human *INSL3* gene. Furthermore, because INSL3 is expressed in a differentiated testis, any factor that influences Leydig cell differentiation may also affect INSL3 expression and thereby cause cryptorchidism.

Treatment of pregnant mothers with diethylstilbestrol as a hormonal support during pregnancy was abandoned owing to a high rate of cryptorchidism and other genital defects (Stillman, 1982). The effect of environmental xenoestrogenic compounds has also been linked to the recent rise in cryptorchidism in humans (Toppari and Skakkebaek, 1998). In one study, mice were treated with diethylstilbestrol to induce cryptorchidism in male neonates (Emmen et al, 2000; Nef et al, 2000). It is interesting to note that the treated animals demonstrated a complete suppression of testicular *Insl3* expression on embryonic days 16 and 18.

The male knockout mice for the transcription factor *Hoxa-10* gene are viable but infertile. While they are normally virilized, they are bilaterally cryptorchid with a severely underdeveloped gubernaculum. Fetal localization studies have shown that *Hoxa-10* is expressed in the gubernaculum, as well as in the kidneys, but not in other reproductive tissues. Although its function and role are not

yet established, it appears to be another candidate regulatory gene for gubernacular development and testicular descent.

The spinal nucleus of the genitofemoral nerve (GFN) is located at L1-2 in the spinal cord and is sexually dimorphic (Goh et al, 1994). Transection of the GFN produced cryptorchidism (Lewis, 1948), and the initial thought—now proven faulty—was that the cremasteric muscle paralysis caused by denervation led to an abnormal traction of the testis through the inguinal canal. When this observation was revisited many years later, it was speculated that androgens may act via the GFN (Beasley and Hutson, 1987). The GFN innervates the gubernaculum from its posterior and caudal surface, so that distal transection would cause denervation of the gubernaculum (Tayakkanonta, 1963). Additional supporting evidence for the role of the GFN comes from the analysis of patients with spina bifida and animals with spinal cord transection (Hutson et al, 1988). In more than 300 boys with spina bifida, 23% had cryptorchidism, with a higher incidence found in those whose defect was higher than L4. In rats with neonatal spinal cord transection, approximately 40% had cryptorchidism when the lesions were midlumbar. Anatomic studies of the GFN identified calcitonin gene–related peptide (CGRP) as the primary neurotransmitter (Goh et al, 1994). The effect of CGRP on the rodent gubernaculum has been studied extensively. In male neonatal rats under anesthesia, the gubernaculum, which has not yet reached the scrotum, contracts rhythmically; this is enhanced by increased intra-abdominal pressure and direct application of exogenous CGRP (Park and Hutson, 1991). In organ culture, neonatal rat gubernaculum responds to CGRP in a dose-dependent manner but not to other neuropeptides (Park and Hutson, 1991). Although these findings are raising a strong speculation for the role of CGRP, its significance in human testicular descent remains uncertain.

The ovaries also descend and become suspended within the broad ligaments of the uterus. As in males, the female embryos develop a gubernaculum-like structure extending initially from the inferior pole of the gonad to the subcutaneous fascia of the presumptive labioscrotal folds. This “female gubernaculum” later penetrates the abdominal wall as part of a fully formed inguinal canal and becomes the *round ligament*. In females, although the gubernaculum does not shorten like that in males, it still causes the ovaries to descend during the third gestational month (by anchoring the ovaries in the pelvis) and places them into a peritoneal fold (the *broad ligament* of the uterus). This translocation of ovaries appears to occur during the seventh week when the gubernaculum becomes attached to the developing paramesonephric (müllerian) ducts. As the paramesonephric ducts fuse together in their caudal ends they sweep out the broad ligaments and simultaneously pull the ovaries into these peritoneal folds. In the absence of androgens, the female gubernaculum remains intact and grows in step with the rest of the body. The inferior gubernaculum becomes the round ligament of the uterus and attaches the fascia of the labia majora to the uterus, while the superior gubernaculum becomes the ligament of the ovary, connecting the uterus to the ovary. As in males, the processus vaginalis of the inguinal canal is normally obliterated, but occasionally it remains patent to become an indirect inguinal hernia.

Molecular Mechanism of Sex Development

At the beginning of gestation (first and second week in humans), embryos of the two sexes differ only by their sex chromosomes. The first visible sign of sexual dimorphism in mammalian embryos is when the bipotential gonad starts to develop into either a testis or an ovary in XY and XX individuals, respectively. This occurs at around 6 weeks of development in humans. Differentiation of the gonads leads to testicular and ovarian hormone production and subsequent induction of anatomic and physiologic differences.

Mammalian sex development involves a complex interplay of multiple cell types that occurs in a narrow window of time. Thus it is important to understand the temporal and spatial patterns of gene expression as well as the anatomic sequence of tissue movement and differentiation.

Both testis and ovarian development involve sex-specific pathways that appear to act antagonistically to one another. The normal role of *SRY* in XY gonads is to tip the balance in favor of the testis-specific pathway. *SRY* expression initiates an upregulation of *SOX9* expression. In mice, *Sox9* has been shown to stimulate *Fgf9* expression and subsequently, both FGF9 and SOX9 act together in a positive feedback loop and are thought to suppresses *Wnt4* (by unknown mechanisms), leading to the establishment of the testis-specific pathway. In the absence of *SRY* in XX individuals, *RSPO1* and *WNT4* are expressed at high levels and stabilize cytoplasmic β -catenin, which is then translocated into the nucleus, where it binds to the TCF/LEF (transcription factor/lymphoid enhancer-binding factor) and activates the transcription of target genes. Both *WNT4* and β -catenin suppress (by unknown mechanisms) the *SOX9*/FGF9 positive feedback loop, allowing the ovarian-specific pathway to progress.

In both sexes, before the expression of the male-determining gene *SRY*, a number of factors appear to play a role in urogenital ridge specification (Fig. 122-27). Because the urogenital ridge is the

Figure 122-27. Molecular mechanism of male and female genital development. *SF1* and *WT1* expression is critical for genital ridge specification. *SRY* and *SOX9*, influenced by *GATA4* and *Fog2*, are important factors for specifying the differentiation of Sertoli cells. *SF1* is also critical in the regulation of müllerian-inhibiting substance (MIS) and other genes involved in androgen synthesis. No specific female factors have been identified, but *Wnt4* and *DAX1* are expressed with unique female patterns. DHT, dihydrotestosterone.

primordium for the gonad, kidney, and reproductive tract, multiple organs are affected by mutations of these genes. In the mouse gonad, *Wt1* is expressed early, suggesting a role in specifying coelomic epithelial cells in the development of urogenital ridge. The *Wt1* homozygous knockout mice do not form kidney, adrenal, or gonad cells (Kreidberg et al, 1993). Humans heterozygous for mutations in *WT1* exhibit abnormalities of the genital system in addition to abnormalities in renal development, including WAGR syndrome, Denys-Drasch syndrome, and Frasier syndrome. *WT1* appears to function upstream of *SF1* (steroidogenic factor 1) and *DAX1* (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X chromosome) (Wilhelm and Englert, 2002). *Wt1* and *Sf1* enhance transcription of mouse *MIS* gene, whereas *Dax1* appears to suppress this interaction (Nachtigal et al, 1998). *SF1* also regulates the expression of other genes involved in male differentiation, steroidogenesis, and reproduction (Achermann et al, 2001). Although *SF1* stimulates *DAX1* transcription (Ikeda et al, 1996), *DAX1* in turn acts as a transcriptional repressor of *SF1*-regulated genes (Ito et al, 1997). In *Sf1* knockout mice, neither XX nor XY animals form gonads, and cells in gonadal remnant undergo apoptosis, suggesting that *SF1* is a necessary survival factor for early progenitors of a developing gonad (Luo et al, 1994). Data suggest that *SF1* and *DAX1* are both independently important for normal male gonadal differentiation. Other candidate genes have also emerged based on mouse gene deletion models and embryonic expression studies, although their functional significance in gonadal development is not fully elucidated yet; they include *Emx2*, *M33*, *Lhx9*, *Pod1*, *Dmrt1*, *Mro*, *Pn1*, and *Vn1* (Park and Jameson, 2005).

Mammalian embryos remain sexually undifferentiated until the time of sex determination. When the Y-linked master regulatory gene, called *SRY* (the sex-determining region of the Y chromosome), is expressed in the male, the epithelial cells of the primitive sex cords differentiate into Sertoli cells, and this critical morphogenetic event triggers subsequent testicular development. Once the testes are established, they produce androgens to give rise to the male phenotype. In the female gonads no morphologic change is observable at the time of *SRY* expression. It follows from this general picture that in mammals, sex determination is synonymous with testicular development, with the differentiation of Sertoli cells being the key event (McLaren, 1991). After three decades of search for the elusive mammalian testis-determining gene, the *SRY* gene was discovered in 1990 by Sinclair and colleagues (Sinclair et al, 1990). Since then, research has focused on identifying the putative regulatory mechanism operating downstream of *SRY* and the genetic control of *SRY* expression.

Although it has been known since 1921 that human males have an X and Y chromosome, the role of these "sex" chromosomes in human sex development was not elucidated until 1959. This question was answered by the examination of two individuals with unique chromosome abnormalities: one female with Turner syndrome (45,XO karyotype) and one male with Klinefelter syndrome (47,XXY karyotype). By 1966, analysis of many structurally aberrant Y chromosomes in humans led to the conclusion that the information necessary to initiate the male phenotypic development was present on the short arm of the Y chromosome. The identity of the protein encoded by the testis-determining region of the Y chromosome proved elusive. In the mid 1980s the DNA of sex-reversed males with 46,XX karyotype was examined. The genome in these individuals was found to contain small amounts of Y chromosome that had been translocated onto the X chromosome. Analysis of this DNA narrowed the location of the *SRY* to a relatively small region within the short arm of the chromosome. The role of *SRY* in human sex development has been further supported by studies using mice (Greenfield and Koopman, 1996). The comparable genetic locus in mice (*Sry*) is activated and expressed in the genital ridge 11.5 days after coitus, just before the initiation of testicular development. Moreover, when the DNA of female XY mouse chromosomes was analyzed with specific DNA probes for *Sry*, this locus was absent. Of greatest importance, it has been demonstrated that insertion of *Sry* into one of the X chromosomes of genetically female mouse

embryos converted these mice to phenotypic males (Koopman et al, 1991). These transgenic “female” mice exhibited testes, vas deferens, and an absence of the female reproductive tract. It was thought that identification of the SRY protein would rapidly lead to the identity of downstream elements regulating male sexual development. However, the binding of SRY protein to other genes or factors has not been demonstrated, and the molecular mechanism by which genes interact to determine sex remains speculative. Deletions of the SRY gene in humans cause XY male-to-female sex reversal, whereas SRY translocations to the X chromosome lead to XX female-to-male sex reversal (Harley et al, 2003). In the mouse, *Sry* expression occurs in a narrow temporal window in the developing Sertoli cells. The central region of the gonad demonstrates *Sry* expression first, followed by cephalad to caudal progression along the entire length of the gonad (Bullejos and Koopman, 2001). A closely related gene, *SOX9*, is the other definitive male-determining gene identified thus far. *SRY* and *SOX9* expression overlaps in cells of the Sertoli lineage. As the *SRY* expression diminishes, *SOX9* expression increases in the male. *SOX9*, which is weakly expressed in the undifferentiated gonad, is downregulated in the female (Sekido et al, 2004). Transgenic expression of *Sox9* in XX mice is sufficient to induce female-to-male sex reversal and male differentiation (Vidal et al, 2001). Heterozygous human *SOX9* mutation leads to campomelic dysplasia, a severe skeletal disorder with defective cartilage development; many of these patients have dysgenetic gonads (Foster et al, 1994). These individuals possess a normal *SRY* but may exhibit completely feminized genital structures. *Sox9* knockout mouse embryos have elevated levels of *Sry* expression, suggesting a possible negative feedback regulatory loop that downregulates *Sry* (Chaboissier et al, 2004). *GATA4* and *Fog2* are important in cardiac development but also appear to affect gonadal development as well. *GATA4* mutation eliminates expression of male differentiation markers *Sox9* and *MIS*. *Fog2* knockout mice have decreased expression of *Sry* and loss of *Sox9*, *MIS*, and *desert hedgehog*, but persistence of female gonad marker *Wnt4* (Tevosian et al, 2002). Similarly, triple mutants for insulin receptor, insulin-related receptor, and *Igf-1* receptor have low *Sry* and *Sox9* expression and exhibit male-to-female sex reversal, implicating a role for an insulin signaling pathway (Nef et al, 2003).

Proliferation of Sertoli progenitor cells is an important event in male gonad development, a process driven by *SRY* expression (Schmahl et al, 2000). One paracrine factor linked to this proliferation is FGF9. *Fgf9* knockout mice demonstrate varying degrees of male-to-female sex reversal (Colvin et al, 2001). In addition, FGF9 is a candidate male gonad-specific chemoattractant paracrine signal that induces migration of cells from the mesonephros (endothelial and peritubular myoid cells) into the gonad (Martineau et al, 1997). Migration of these cells is critical for the development of testis cord formation (Buehr et al, 1993) as well as *SOX9* expression (Tilman and Capel, 1999). Such migration is absent in females, presumably owing to absence of chemoattractants.

Once sex determination has occurred, the subsequent phenotypic differentiation depends mostly on the production of androgens. As bipotential gonad differentiates into testis, *Sf1* expression becomes restricted to Leydig cells and mediates expression of several gene-encoding enzymes that are required for testosterone biosynthesis, including *StAR*, *Cyp11a1*, *Cyp17*, and *3βHSD*. Factors for Leydig cell determination are not known, and, moreover, Leydig cell origin, whether from immigrant mesonephric cells or progenitors within the gonad, remains speculative. There is evidence that Leydig cell fate is dependent on paracrine signals (Yao et al, 2002; Brennan et al, 2003).

Relatively few genes have been shown to exhibit a female-specific pattern of gene expression early in gonadal development. Thus far, no female-determining gene has been identified. The *DAX1* gene was initially suggested as a pro-ovarian (or anti-testis) candidate gene because its duplication on an XY background was associated with impaired testicular development (Bardoni et al, 1994; Swain et al, 1998). However, loss of *DAX1* in XX background does not prevent ovary development (Yu et al, 1998). The list of

genes that demonstrate ovary-specific expression patterns is growing; these include *Fst* and *Stra8* (Park and Jameson, 2005). It has been postulated that there is a “Z-factor” that suppresses proteostic events in both XX and XY backgrounds (McElreavey et al, 1993). According to this hypothesis, the Z-factor, which normally suppresses testicular determination, is repressed by *SRY* in males, and in females, owing to absence of *SRY*, it will inhibit testicular development. Loss of the Z-factor in the XX background will result in female-to-male sex reversal, but gain-of-function in XY background may or may not result in male-to-female sex reversal, depending on whether the Z-factor can override the suppression effect of *SRY*-driven signaling. One candidate for such a Z-factor is *Wnt4*. XX mice deficient for *Wnt4* develop testis-like differentiation and nephric (wolffian) duct derivative (Vainio et al, 1999). It is curious to note that their external genitalia remain female. Furthermore, *Wnt4* is downregulated in males, whereas its expression remains strong in females (Yao et al, 2004). R-spondin 1 (*RSPO1*) encodes a secreted factor that can stabilize β-catenin as part of the canonical Wnt-signaling pathway and is expressed at high levels in mouse as well as human gonads around the critical time of gonad development. Its role in ovarian development was first implicated when a homozygous single nucleotide insertion within the *RSPO1* coding sequence was identified in four 46,XX testicular disorders of sex development (DSD) patients from a consanguineous family. In addition, a homozygous exonic deletion was identified in an unrelated sporadic case of 46,XX testicular DSD. In 46,XX female individuals, both *WNT4* and *RSPO1* are known to promote ovarian development and repress testis development (Parma et al, 2006).

KEY POINTS

- The genitourinary system develops from three embryonic sources: intermediate mesoderm, mesothelium of coelomic (future peritoneum) cavity, and endoderm of the urogenital sinus.
- The urinary system begins its development before the genital system development becomes evident. With the formation of nephric ducts, embryonic kidneys develop sequentially in the order of pronephros, mesonephros, and metanephros.
- The permanent kidney, the metanephros, develops as a result of inductive interactions involving the ureteric bud (an outgrowth of nephric duct), condensing blastema of metanephric mesenchyme, and stromal cells. The renal tubulogenesis occurs via mesenchymal-epithelial conversion, whereas dichotomous branching of the ureteric bud leads to the formation of the collecting system.
- The bladder and urethra develop from the endodermal urogenital sinus, which is an anterior portion of the cloaca after it becomes separated from the posterior anorectal canal.
- Morphologically, the genital development takes place about 3 weeks after the start of the urinary system development. Sexual dimorphism begins to take shape at about the seventh gestational week. Primordial germ cells migrate from the wall of the yolk sac to invade the posterior mesenchyme to establish the gonadal ridge.
- In males, driven by the *SRY* gene of the Y chromosome, mesenchymal cells of the developing testis differentiate to become the Sertoli cells. Sertoli cells produce *MIS* to cause degeneration of female müllerian ductal structures while stimulating the development of testosterone-producing Leydig cells. Under the influence of testosterone, male external genitalia develop, as well as prostate and other male accessory sex glands.
- Both gonads descend to pelvic location by the third month, but the testis descends into the scrotum with the aid of the gubernaculum at about the seventh month.

Development of Renal Function and the Transition to Neonatal Life

Renal Homeostasis, Fluids, and Electrolytes

Clinical Presentation of Renal Dysfunction

Renal Replacement Therapy

Summary

While pediatric urologists and pediatric nephrologists train through very different pathways and are often thought by many in medicine to practice their crafts in relative separation, in fact the two specialties are tightly linked through the anatomic and functional effects of urinary tract malformations and acquired diseases. This chapter is designed to highlight areas of clinical practice wherein the collaborative expertise of nephrologists and urologists can best benefit acute and chronic patient care.

DEVELOPMENT OF RENAL FUNCTION AND THE TRANSITION TO NEONATAL LIFE

Nephrogenesis and Anatomic Development

The development of the human kidneys and urinary tract begins extraordinarily early in human development with the metanephric kidney appearing during the fifth to sixth week of gestation as the ureteric bud epithelium branches from the wolffian duct. **Nephrogenesis completes in utero at 36 weeks of gestation with approximately two thirds of nephrons developing in the third trimester.** Concomitant lower urinary tract development occurs from 8 to 10 weeks of gestation; urine production begins around 10 weeks of gestation. The process of centrifugal maturation of the kidneys results in deeper, juxtamedullary nephrons that are larger, more mature, and more completely functional than “younger” developing outer glomeruli at the time of birth (Fig. 123-1). The complex genetic, epigenetic, and biochemical pathways of induction, differentiation, and functional development are areas of significant research progress but remain unclear, and the vast majority of kidney and urinary tract malformations and “acquired” diseases remain with poorly understood etiologies and pathologic mechanisms and minimal therapeutic options. The majority of congenital renal and urinary tract disorders have anatomic and functional abnormalities of both the kidneys and the urinary tract, many with “mixed” anomalies including dysplasia, cystic malformations, varying degrees of obstruction or vesicoureteral reflux, and voiding dysfunction. The inter-relationships between the individual anomalies and the resultant final patient phenotype with progressive chronic renal disease remain unclear but are areas where collaborating pediatric nephrologists and urologists are likely to provide enhanced patient care through appreciation of the complexity of the overall picture and understanding of how expectant or therapeutic management can be expected to affect the final physiologic phenotype.

Hemodynamics, Glomerular Filtration Rate, and Tubular Function

As fetal life progresses, renal blood flow, glomerular filtration rate (GFR), tubular function, and urine flow all increase in magnitude and regulatory sophistication, although blood flow remains highest in the medulla and minimal in the developing cortical regions. It should be noted that renal blood flow and GFR are only 10% of those of an adult at the time of term delivery and are even lower in premature infants. **However, perinatal redistribution of renal blood flow leads to increases in cortical blood flow that, along with increased arterial pressure, glomerular permeability, and filtration surface area, result in a doubling of GFR in healthy infants by around 2 weeks of postnatal life.** For the first day or so after birth, creatinine values in infants reflect maternal renal function alone, but creatinine should never rise in a term newborn. Healthy term neonates will have a serum creatinine below 1.0 mg/dL by 1 week of age and will continue to decrease to around 0.3 mg/dL by 1 to 3 months after birth. Preterm infants, with “unfinished” nephron development, can be expected to have higher creatinine values (inversely proportional to gestational age) and slower decreases to 0.4 to 0.8 mg/dL by 6 months (Alinei and Guignard, 1987; Finney et al, 2000). It is now believed that many extremely premature infants may not normally complete nephrogenesis because of the multitude of perinatal and postnatal events and exposures following a preterm delivery, and these apparently small increases in creatinine may actually represent chronic kidney disease (CKD) caused by nephron deficits (Carmody and Charlton, 2013).

Fetal urine output increases exponentially during the second half of gestation to around 1.0 mL/min at birth but then rapidly declines to around 0.1 mL/min after delivery, reflecting the need to conserve water. However, neonatal urinary concentrating capacity is still quite limited by a short loop of Henle, low NaCl transport in the ascending limbs, low urea generation, and decreased response to arginine vasopressin (Ames, 1953). All of these functional activities of the nephron increase progressively through the first year or two of life to reach adult levels, but the overall immaturity of these operations places the infant at high risk for loss of fluid and electrolyte homeostasis if challenged by illness, overload, or depletion.

Neonatal sodium balance is also characterized by a progressive increase in reabsorptive capacity, a relatively slow excretory response to a sodium load, and very importantly, overall positive sodium

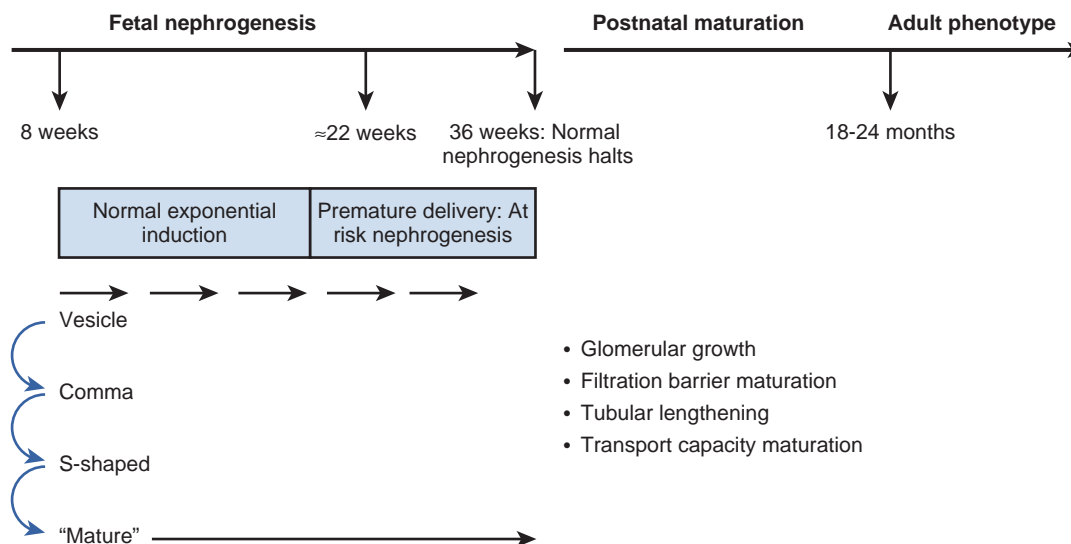

Figure 123-1. Time frame of nephrogenesis and renal maturation noting the extensive expected morphogenetic interval at risk in the event of preterm delivery.

balance needed for normal growth. However, premature infants, with even more immature mechanisms to control these factors, have higher obligatory sodium losses (as high as 5% or more in those infants <30 weeks of gestation) owing to relatively poor proximal and distal tubule transport functions and responses to aldosterone that eventually improve (Feld and Corey, 2004). In the meantime, many premature infants will require sodium supplementation to support normal growth.

Other tubular functions such as control of potassium, phosphate, calcium, and acid-base homeostasis are also less efficient in newborn infants than in adults, with preterm infants even more challenged by these tasks. Urinary phosphate excretion is low as a result of poor tubular responsiveness to parathyroid hormone, and calcium excretion is high, most likely linked to relatively poor sodium reabsorption (Webster and Haramati, 1985). Potassium excretion is limited by a number of factors, including unfavorable electrochemical gradient in the principal cells, low membrane permeability to K^+ , low tubular flow rates, and low sensitivity to mineralocorticoids (Benchimol and Satlin, 2004). Acid-base balance is also different in the newborn than the older child and adult, and infants have lower blood pH and bicarbonate levels because of a reduced threshold of HCO_3^- in the proximal tubule. Similarly, infants are unable to maximally acidify the urine by generation of ammonium, leading to additional low-level acidosis (Quigley and Baum, 2004).

Clinical Correlates

Effects of Obstruction/Maldevelopment on Transition

It should be noted that kidneys are not required for fetal survival as all solute and electrolyte control can be managed by exchange across the placenta. However, fetal urine output is mandatory for in utero airway branching and alveolar development such that low urine output states, whether from renal developmental catastrophes or obstructive lesions, result in pulmonary hypoplasia that may not be sufficient to sustain postnatal life or may not allow for life without pulmonary support systems. Unfortunately, the quantitation of amniotic fluid volumes and the assessment of fetal pulmonary development remain challenging and relatively inaccurate, making prognostic determinations extremely difficult unless multiple serial assessments are feasible.

Given the relative immaturity of the majority of all glomerular and tubular functions in the full-term newborn and even greater immaturity in the preterm infant, any additional processes that

compromise function can have significant impacts on the overall well-being of the neonate. Hypoxia, hypovolemia, hypoperfusion, nephrotoxic drugs, and fluid/electrolyte deficits or overloads all lead to more dramatic alterations in renal function and fluid and electrolyte balance during early infancy, and acute kidney injury (AKI) may have deleterious long-term effects that are not as apparent in the mature kidney exposed to the same challenges. The effects of kidney injury suffered in the neonatal period have been minimally studied in human adults, and since many of those injuries were not isolated to the kidneys, it is very challenging to determine causality; however, as we become more and more adept at saving the lives of the most extremely premature infants, we must be attentive to saving the long-term function of all organ systems.

Effects of Nephron Endowment

While in vivo determination of nephron number remains elusive, it is apparent that genetic endowment of nephron number is quite variable. Because functional nephron number declines consistently beginning in early adulthood (Winearls and Glasscock, 2011), it is logical that higher initial nephron counts may result in better long-term preservation of renal function in adulthood and through modern society's consistently lengthening life span. In a similar fashion, starting with lower nephron numbers may lead to the development of clinically significant renal insufficiency over time, a process that would clearly be exacerbated by the addition of acquired disease or other life events that cause renal damage, even if quantitatively small at the time. Since well over half of the genetically determined nephrons are formed after 30 weeks of gestation (Hinchliffe et al, 1991), pediatric practitioners should be additionally attuned to the continually increasing deleterious effects of premature delivery added to anatomic urinary tract defects plus recurrent illness, medication use, and other physiologic stressors. These synergistic effects are often subtle and masked by hyperfiltration of remaining nephrons, with clinically observable functional compromise occurring sometimes severely and rapidly when compensatory mechanisms are finally unable to maintain homeostasis. The long-term functional effects of decreased nephron number, whether determined by development or altered by disease or illness later in life, should be a point at which pediatric nephrologists and urologists should consistently focus together; preservation of remaining nephrons is important for everyone. Procedures that remove remaining nephrons should be very carefully considered and acute events that risk remaining nephrons should be aggressively managed.

RENAL HOMEOSTASIS, FLUIDS, AND ELECTROLYTES

Glomerular Filtration Rate, Tubular Function, and Hemodynamics

As described earlier, the transition from fetal to postnatal life is a period of rapid change in renal hemodynamics, filtration capabilities, and tubular function, with the majority of capabilities near adult levels by 6 to 12 months. Only fine-tuning of these processes occurs over the second 12 months of life. However, maturation of these functions is slowed by prematurity, anatomic abnormalities of the urinary tract, and other systemic illness such that the infants seen by pediatric urologists will very often have notable “developmental delays” in expected renal functional capacity. Recognition that apparently small changes in laboratory values may indicate significant underlying dysfunction can encourage special attention to drug choice, dosing, and monitoring; close observation of responses to fluid prescriptions; and rapid appropriate adjustments to the original plan. Indeed, many patients seen by the pediatric specialist will have subtle functional abnormalities that may be evident only when the stress of an acute event meets “normal” management practices. Since renal functional capacity never increases after the early events of the first 2 years after birth, the astute clinician is permanently wary of the child who exhibits any signs of functional insufficiency.

The measurement of GFR in infants remains difficult. Standard measurements of GFR by creatinine clearance or iothalamate/iohexol/inulin clearance are difficult because of the need for timed urine collections and timed blood draws and poor availability of laboratory assays. Nuclear imaging options also require accurate intravenous injections, timing, and data collection and results are not tightly reproducible in young children. Measurement of serum creatinine (also challenged by the multiple options of chemical assessment) remains the most common clinical approach to estimation of GFR using the Schwartz equation to correct for body mass (Schwartz et al, 2009). The use of serum cystatin C for measurement of GFR is gaining popularity as it is not excreted by the renal tubule and therefore is more accurate in settings of renal dysfunction, but it is not yet routinely available with rapid turnaround (Filler et al, 2002). In the meantime, clinicians should recognize that (1) creatinine change is a slow and relatively inaccurate marker of changes in GFR, especially when steady state is not achieved; (2) other indicators of renal function (fluid balance, electrolyte changes) may also indicate significant functional impairment; and (3) careful and accurate measurement of GFR may not be necessary in usual clinical practice but should be mandatory in research situations where functional outcomes are of primary interest.

Manifestations of Renal Immaturity

The reduced functional capacity of immature kidneys complicates the physiologic responses to external stress. The inability to maximally concentrate the urine contributes to the development of dehydration in the presence of illness or volume restriction, while the inability to maximally dilute the urine results in a slowed response to large fluid infusions and subsequent hyponatremia and volume overload. The hallmark of developmental proximal tubular “dysfunction” is acidosis resulting from suboptimal reabsorption of filtered bicarbonate, while distal tubular dysfunction is marked by relatively poor potassium secretion and resultant hyperkalemia. Metabolism and clearance of medications is often slowed in early childhood, and many drugs have unfortunately never been adequately studied for use in the young child. All of these developmentally normal concerns are exacerbated in the presence of renal anomalies.

The aberrantly formed tubules of dysplastic kidneys are unable to maximally reabsorb sodium or concentrate the urine, and obstructive nephropathies are commonly marked by aldosterone resistance of the distal tubule and subsequent hyperkalemia and acidosis. Therefore relatively mild childhood illnesses commonly result in dehydration with significant electrolyte disarrays in infants and children with underlying renal disease.

Fluid Prescriptions

Fluid and electrolyte prescriptions for hospitalized children unable to take enteral fluids are a mainstay of clinical care. In general, these prescriptions are a combination of “maintenance,” “replacement,” and “anticipated losses.” By definition, “maintenance” fluid needs are based on weight or body surface area and preserve homeostasis by correcting the obligatory daily losses of water and solute that occur at basal state. “Replacement” fluids and electrolytes are those needed to correct for losses occurring from acute illness, including vomiting, suctioning, diarrhea, third spacing, fever, excessive sweating, burns, and bleeding. Practitioners planning ahead also include “ongoing anticipated losses” and utilize additional fluids and electrolytes to proactively prevent dehydration or electrolyte disarray from expected outputs such as third-space drainage, ostomy losses, nasogastric suctioning, and continued vomiting.

In healthy young children, maintenance needs are based on normal energy expenditure and logically reflect the water and electrolyte content of human and cow’s milk as converted to hypotonic saline solution (0.2% [or ¼ normal] saline in 5% dextrose in water with 10 to 20 mEq/L of potassium chloride) (Holliday and Segar, 1957). However, the use of these fluids has recently become controversial because of the recognition of complications of hyponatremia in hospitalized patients (Holliday et al, 2003; Beck, 2007; Moritz and Ayus, 2007). The argument is centered on the classic “maintenance requirements,” which were derived for *healthy* children, while the usual hospitalized child, especially in today’s tertiary care centers, is often far from “healthy.” The frequency of nonosmotic stimuli of antidiuretic hormone (ADH) secretion (syndrome of inappropriate ADH secretion) is likely under-recognized; inappropriate ADH secretion occurs with malignancies, meningitis and other central nervous system disorders, pneumonia and other causes of respiratory distress, pain, postoperative situations, and a number of medications. It remains to be determined whether the development of hyponatremia in these circumstances is the result of the use of hypotonic fluid per se or of an overload of free water from inaccurate estimation of needs and/or inappropriate ADH secretion. However, many now advocate the use of isotonic saline as maintenance fluid in hospitalized children (Wang et al, 2014). **The astute pediatric urologist should not accept these recommendations without recognizing that none of the few studies comparing hypotonic versus isotonic fluids for maintenance use was performed in children with renal disease.** Given the challenges of the damaged kidney in managing salt and water overload and the high incidence of hypertension in this population, fluid

KEY POINTS: KIDNEY DEVELOPMENT

- Kidney and urinary tract development occur simultaneously and normal functional development is likely to be integrated across the system.
- Insufficient amniotic fluid adversely affects fetal lung development, resulting in a newborn with more than just kidney disease. The presence of adequate pulmonary function is usually associated with reasonably adequate renal function (for the short term).
- Renal and urinary tract maldevelopment can be expected to slow the normal postnatal changes in GFR and blood flow—patience is warranted.
- Nephron number itself may be critical for maintenance of long-term renal capacity. Developmental events that decrease nephron endowment or postnatal illnesses or procedures that reduce nephron number are likely to result in increased long-term risk for CKD.

and electrolyte prescriptions should be carefully tailored to individual patient needs and risks and constantly monitored.

KEY POINTS: MANIFESTATIONS OF RENAL IMMATURITY

- Control of fluid and electrolyte homeostasis evolves across the developmental spectrum of the newborn, infant, and young child, leaving the youngest and most immature children at highest risk for metabolic disarray.
- The presence of urinary tract anomalies and chronic renal dysfunction often prevents or delays the normal developmental improvements in glomerular and tubular function, often in complex ways.
- The management of fluids and electrolytes in children with urinary tract anomalies and chronic renal dysfunction should *not* be approached purely with algorithmic approaches that were designed for treatment of acutely ill children without renal disease. Individualized consideration of water and solute balance is needed for best practice.

CLINICAL PRESENTATION OF RENAL DYSFUNCTION

Hematuria

Hematuria is one of the most common reasons for referral to pediatric nephrologists and pediatric urologists. It is a fairly common finding, and the large differential diagnosis list is rather intimidating and time-consuming for many primary care physicians. Multiple studies have shown that the incidence of detecting blood in the urine ranges from 0.5% to 3% of evaluated children (Hogg, 2009), with results influenced by the definition of significant hematuria and the local practices for screening urinalyses. Only approximately 1 in 4 of these children will be found to have persistent hematuria on repeated testing (Vehaskari et al, 1979). Of children evaluated and followed with *persistent* hematuria lasting more than 6 months, two thirds had isolated hematuria only and 70% of those experienced eventual resolution. Of this cohort, 20% were diagnosed with hypercalciuria and/or stone disease, and only 10% were eventually diagnosed with chronic glomerulonephritis by biopsy after the additional development of proteinuria (Türi et al, 1989). This evidence provides **strong support for the concept that isolated microscopic hematuria is usually a benign condition that can be confidently diagnosed once relatively simple histories and assessments have been accomplished.**

While the vast majority of cases of hematuria are microscopic in nature, the development of asymptomatic gross hematuria is more likely to result in urgent referral and more aggressive evaluation. Studies suggest that two thirds of these evaluations will result in identification of an etiology for the hematuria, but one third of cases will remain enigmatic (Youn et al, 2006; Greenfield et al, 2007). While the frequency of individual diagnoses will vary between those patients seen by urologists and nephrologists, with more patients seen by urologists diagnosed with trauma and urinary tract infection and those seen by nephrologists more commonly diagnosed with glomerulonephritis, the differential diagnosis lists for macro- and microhematuria are essentially identical (Box 123-1).

Evaluation

Gross hematuria warrants acute evaluation while the detection of microhematuria warrants watchful waiting for several months in the absence of concerning history, physical examination findings, and proteinuria. Many patients, but not all, will come to specialty care with parts of the basic evaluations completed (Fig. 123-2).

Important elements of the history include timing of onset of the hematuria; persistence or intermittent nature; correlation with illness, exercise, or trauma; and the presence or absence of other symptoms, including abdominal/flank pain, dysuria/urgency, rash,

BOX 123-1 Causes of Hematuria in Children

MACROSCOPIC

Transient
Hypercalciuria/nephrolithiasis

Glomerulonephritis (all types)
Cystitis/pyelonephritis
Exercise
Congenital anomaly of urinary tract
Thin basement membrane disease
Drugs
Interstitial nephritis
Sickle cell disease/trait

swelling, joint symptoms, and headaches/vision changes (which may be associated with hypertension). Is the bleeding evident throughout voiding (as would be expected for glomerular or bladder bleeding) or is it at the end of voiding, indicating urethrorrhagia? The family history should be explored for evidence of hematuria, stone disease, CKD of any form, deafness, bleeding abnormalities, or sickle cell disease. The physical examination should be broad but with special attention to blood pressure, generalized rash, edema, perineal trauma, or abdominal, flank, or suprapubic tenderness.

The most critical diagnostic test is a fresh urinalysis—red blood cells and crystals degrade in stale urine. The urine should also be evaluated for protein, leukocytes, or nitrates. Microscopic evaluation should confirm more than 5 red blood cells per high-power field and should also note the presence or absence of crystals. Children without confirmed microhematuria on secondary evaluation should be considered to have transient hematuria and do not require ongoing evaluation. Glomerular causes of hematuria will be associated usually with brownish or greenish coloration of the urine, and red blood cell casts and dysmorphic red blood cells will be seen. Nonglomerular bleeding is more commonly reddish in color, there are no red cell casts present, and the red cells are uniform in size and shape, although crenation in concentrated urine may cause symmetrical shrinkage. Patients with suggestive symptoms or urinalysis findings consistent with infection should have a urine culture performed. Since hypercalciuria is one of the more commonly diagnosed causes of microhematuria, random urine samples sent for calcium and creatinine are warranted, with hypercalciuria diagnosed at ratios greater than 0.2 for children more than 5 years of age and greater than 0.4 for children ages 2 to 5 years (Sargent et al, 1993). Renal and bladder ultrasound examinations are used to screen for renal parenchymal or bladder causes for hematuria, although the yield in patients with long-standing asymptomatic hematuria is quite low. However, given the benign nature of ultrasonography, it is often used to provide reassurance to physicians and families that no anatomic problem or stone is underlying the hematuria.

Patients with proteinuria, hypertension, or symptoms of systemic disease are likely to have some form of glomerulonephritis

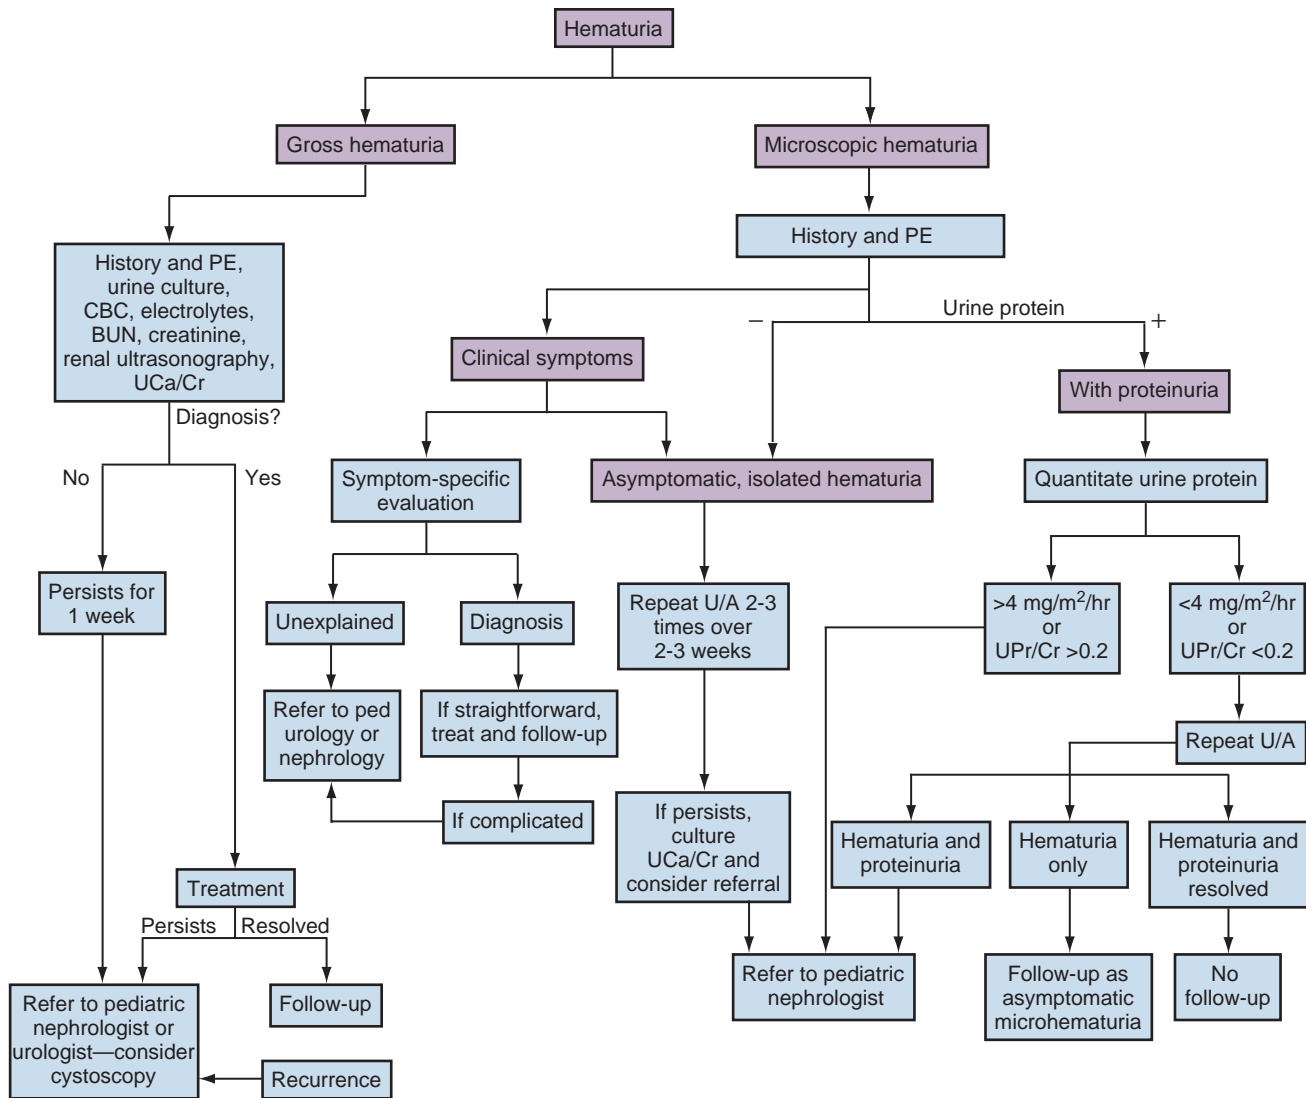

Figure 123-2. Algorithm for the treatment of hematuria. BUN, blood urea nitrogen; CBC, complete blood cell count; PE, physical examination; U/A, urinalysis; UCa/Cr, urinary calcium/creatinine ratio; UPr/Cr, urinary protein/creatinine ratio.

and will most commonly be further evaluated and managed by a pediatric nephrologist, with the initial evaluations including quantitation of urine protein, serum chemistries, blood counts, complement components C3 and C4, and antistreptolysin O. Depending on age (preteen and up) and symptomatology, systemic lupus erythematosus (SLE) serologies may be sent as well. It is important to note that large numbers of red blood cells in the urine may yield low-level positive readings on the urine dipstick for protein. Therefore all patients with gross hematuria should also have quantitative urine protein studies done (random protein/creatinine ratio should be <0.2) as part of their initial evaluations. In the rare instance in which renal ultrasonography indicates the presence of a mass or other anatomic abnormality, further evaluation with computed tomography, magnetic resonance imaging, nuclear imaging, voiding cystourethrography, or cystoscopy may be warranted as indicated by the suspected abnormality. It is important to note that cystoscopy and urethral dilation are *not* warranted for microscopic hematuria (Feld et al, 1998) if the sonogram is normal. Cystoscopy is occasionally beneficial for evaluation of recurrent gross hematuria if it can be performed during an episode of bleeding. Visualization of bleeding from both ureteric orifices indicates a glomerular source while unilateral bleeding suggests an upper urinary tract or vascular anomaly—although many remain resistant to exact diagnosis.

Hypercalciuria is a commonly identified etiology of both micro- and macrohematuria and may be asymptomatic or may be associated with dysuria. Hypercalciuria should be considered in any patient with hematuria, dysuria, and a negative urine culture. In children less than 4 to 5 years old a calcium/creatinine ratio of greater than 0.2 is diagnostic (as is a 24-hour urine calcium excretion of >4 mg/kg), while younger children normally have slightly higher values (up to around 0.5 in normal infants). Hypercalciuria can result from high dietary intake of calcium or sodium but is most commonly idiopathic in nature. It is important to note that calcium excretion can vary with dietary intake of calcium and sodium such that elevated ratios should be confirmed and better quantitated with 24-hour urine collections. Secondary causes should be considered in the appropriate clinical circumstances and include immobilization resulting from trauma (especially in adolescent males), loop diuretic use, renal tubular acidosis (RTA), hyperparathyroidism, malignancies, and sarcoidosis. While the incidence of eventual nephrolithiasis development in patients with hypercalciuria is variable, urine calcium excretion is the factor most associated with eventual stone formation (Bergsland et al, 2012), making preventive strategies of increased fluid intake, sodium restriction, mild protein restriction, and diuretic use worthy of consideration.

Management

The management of asymptomatic hematuria is routinely expectant as the majority of cases will resolve over time. It is important that families be aware that low-level persistent hematuria is not, in and of itself, harmful to renal function or blood counts and is *not* predictive of progressive renal disease (however, associated *proteinuria* is concerning). Patients diagnosed with significant abnormalities of the urinary tract or glomerulonephritis will be managed as appropriate for the specific disorder. A diagnosis of hypercalciuria should result in recommendations for high fluid intake and modest sodium restriction for all patients; thiazide diuretics are usually reserved for patients with dysuria who do not respond to conservative approaches or those with documented nephrolithiasis.

KEY POINTS: HEMATURIA

- Isolated asymptomatic microhematuria (defined as >5 red blood cells per high-power field) in children is most commonly a benign, transient, and self-limited condition.
- Family history of nephrolithiasis or renal disease can help guide the evaluation of hematuria in children.
- Recurrent or persistent microhematuria or gross hematuria requires further evaluation, although concerning abnormalities are uncommon in the asymptomatic patient.
- Cystoscopic examination is rarely indicated for children with hematuria and normal urinary tract imaging.
- Hypercalciuria (calcium/creatinine ratio >0.2 in children >4 years old) is a common cause of microscopic and gross hematuria and should be considered in all cases.
- The presence of significant proteinuria accompanying hematuria is indicative of glomerular disease and requires more aggressive evaluation.

Proteinuria

While the American Academy of Pediatrics discontinued recommendations for routine screening urinalysis for children and it may not be cost-effective (Sekhar et al, 2010), many practitioners maintain the practice and it remains a routine part of most pre-participation physical examinations for athletics (Sox and Christakis, 2005). In the pediatric population, proteinuria may be detected during routine screening, serendipitously as a part of an evaluation for another disorder for which urine studies were sent, or during the investigation of suspected renal or urinary tract disease. The circumstances of diagnosis along with the severity of proteinuria should be the primary guide for further evaluation. **In otherwise healthy patients, low-level positive dipstick evaluations discovered at screening will most likely prove to be transient or false positive on repeat studies.** Patients with medical illness and moderate- to high-level proteinuria should be thoroughly evaluated because they are most likely to have clinically important renal disease.

“Normal” Urinary Protein Excretion

The nephron filters, reabsorbs, secretes, and catabolizes proteins and provides an effective barrier against loss of plasma protein. Permeability of proteins across the glomerulus is dependent on molecular weight (MW) and electrical charge. The majority of small plasma proteins and peptides are freely filtered and then reabsorbed and catabolized quickly in the proximal tubule, whereas proteins of high MW and electronegativity such as albumin or immunoglobulin G (IgG) are poorly filtered but recaptured through the endocytotic receptor megalin (Dickson et al, 2014).

Final total daily urinary protein quantity varies with body mass and renal maturity and is influenced by both glomerular filtration characteristics and proximal tubular function. Normal corrected urinary protein excretion ranges from a protein/creatinine ratio of 0.7 in the immature newborn down to 0.2 or less in the mature individual (Table 123-1). When expressed quantitatively by timed

TABLE 123-1 Normal Urinary Protein Excretion

AGE	PROTEIN EXCRETION (mg/m ² /day): MEAN (RANGE)*	PROTEIN/ CREATININE RATIO (mg/mg)†
Premature infant (<30 days)	182 (8-377)	0.7
Term infant (<30 days)	145 (68-309)	0.7
2 mo-4 yr	100 (37-244)	0.55-0.7 (up to 1 yr) 0.4 (1-2 yr) 0.3 (2-3 yr)
5-10 yr	85 (21-234)	0.2
>10 yr	63 (22-181)	0.15-0.2

†Modified from Guignard J-P, Santos F. Laboratory investigations. In: Avner ED, Harmon WE, Niaudet P, editors. Pediatric nephrology. 5th ed. Philadelphia: Lippincott, Williams & Wilkins; 2004.

urine collections, normal urinary protein excretion is less than 4 mg/m²/hr (100 mg/m²/day) (see Table 123-1).

Etiology

Three sources account for clinically important urinary protein excretion: a breakdown in the glomerular barrier, tubular dysfunction, or excessive plasma protein concentrations that overwhelm the normal reabsorptive process. The most common clinical scenario involves a loss of glomerular integrity and excretion of high-MW proteins, including albumin. Whether caused by congenital or acquired podocyte disorders such as minimal change disease, post-streptococcal glomerulonephritis (PSGN), renal scarring, or long-standing diabetes, the structure and function of the glomerulus is altered such that the filtration barrier is disrupted, resulting in leakage of high-MW plasma proteins. These are the disorders that result in the highest urine protein levels and the features of the nephrotic syndrome, often with progressive loss of renal function.

Tubular proteinuria is characterized by abnormal excretion of the low-MW proteins normally reabsorbed by the proximal tubule. Tubular proteinuria is most commonly seen with AKI, as a side effect of chemotherapy or aminoglycoside use, or with the inherited tubulopathies such as Fanconi syndrome or Dent disease. In the pediatric population, disorders of excessive plasma protein concentrations resulting in overflow proteinuria are rare. However, hemoglobinuria from hemolytic crises, myoglobinuria from rhabdomyolysis, and hypergammaglobulinemic states may all be associated with elevated urine protein.

Measurement

Screening urine studies are routinely performed using semiquantitative dipstick assays. Because the strips change color upon binding of high-MW proteins, false-negative results can occur in very dilute urine samples and in cases of low-MW proteinuria. False-positives can occur in very alkaline urines, concentrated samples, or those contaminated with chlorhexidine or radiocontrast agents. False results can also be obtained with reagent strips that have been inappropriately stored or if appropriate timing between exposure and reading is not maintained. Positive results using dipstick techniques should be followed up with quantitative studies.

Quantitative urine protein determinations are performed using timed urine collections, typically for 24 hours. Such collections must be standardized to urine creatinine content and a sample containing greater or less than 15 to 25 mg creatinine/kg/24 hr

should be considered of suspect quality. Patients with unusually high or low muscle mass or obesity may be difficult to assess, but progress over time can usually be followed using the patient as his or her own control. More recently the use of a protein/creatinine ratio in spot urine samples has gained acceptance, and the availability of age-dependent normative values (see Table 123-1) has made this technique quite popular in spite of approximately 20% error rates (Shaw et al, 1983). Finally, while the test for “microalbumin” is able to detect very low levels of urine albumin, its use should be limited to the assessment of the early phases of diabetic nephropathy because of high cost.

Causes

Proteinuria may best be categorized as transient, orthostatic, or fixed (Box 123-2). Transient proteinuria is defined by the disappearance of urinary protein following one or more positive tests. Transient proteinuria accounts for the vast majority of “cases” of isolated proteinuria and results from heavy exercise, fever, and significant heat or cold stress. The degree of proteinuria is mild to moderate (<1 g/24 hr, protein/creatinine ratio <1.0), and repeated assessments should be made in the absence of the probable stressor prior to more involved evaluation.

Orthostatic proteinuria is the next most frequently diagnosed form of isolated proteinuria and is most commonly seen in otherwise healthy adolescents. By definition, orthostatic proteinuria is that which is present only in the upright position and is not associated with abnormal renal function or hypertension. Its cause is unknown, and it may eventually resolve or may be permanent (Springberg et al, 1982). Recumbent collections or samples will be negative by dipstick with protein levels less than 100 mg/8 to 12 hr (or protein/creatinine ratio <0.2), while the upright collections will be positive by dipstick with protein levels 300 to 900 mg/12 to 16 hr. Orthostatic proteinuria becomes less likely if the total daily

urinary protein content exceeds 1 g/day or if there is any degree of associated hematuria.

Persistent nonorthostatic proteinuria of any degree is indicative of some form of underlying renal disease (see Box 123-2) and should be more thoroughly evaluated. Nephrotic-range proteinuria, defined as greater than 40 mg/m²/hr or 3 g/24 hr, may be due to minimal change disease or any other form of potentially aggressive glomerulonephritis but is uncommon with congenital dysplasia, reflux nephropathy, obstructive uropathy, or tubular disorders. In these processes, the proteinuria is usually mild to moderate (500 to 1000 mg/day). These patients will most commonly be referred to a pediatric nephrologist for continued evaluation.

Evaluation

The evaluation of proteinuria is outlined in Figure 123-3. Otherwise healthy patients with isolated proteinuria found by routine screening should have repeated assessments performed after abstaining from potential causes of transient proteinuria. More accurate assessments with spot protein/creatinine ratios will also clarify false-positive dipstick results in patients with highly concentrated urine samples. Should these values be normal, no further evaluation is necessary. While hematuria occasionally occurs in association with the identical stressors known to cause transient proteinuria, the finding of proteinuria and hematuria should lead to consideration of more significant renal disease unless all issues resolve completely.

In healthy normotensive patients whose isolated proteinuria is confirmed on repeated sampling, evaluation for orthostatic proteinuria should be undertaken. The gold standard for confirmation of orthostatic proteinuria is the “split” 24-hour urine collection. Patients should be instructed to provide two consecutive timed collections, one consisting of daytime/active urine during waking hours and one consisting of nighttime/recumbent urine. Both samples should be submitted for protein and creatinine determinations. **A normal nighttime excretion associated with an abnormal daytime excretion (with the total protein excretion <1 g/day) is diagnostic of orthostatic proteinuria.** Alternatively, first-morning spot samples and midday samples can be assessed using protein/creatinine ratios. While existing data suggest that orthostatic proteinuria is indeed benign even if persistent, many specialists still suggest follow-up testing at least 1 year after the diagnosis in order to confirm the lack of any progression.

Proteinuria is occasionally found during an intercurrent illness or during screening for an invasive procedure, and it is usually transient, the result of the stress of the underlying problem that brought the child to attention. Should high-level proteinuria be detected on screening, accurate quantitation should be performed along with evaluation of serum creatinine and referral to nephrology. In other circumstances, the development of clinical concerns drives the evaluation. Signs and symptoms such as edema, hematuria, hypertension, failure to thrive, growth delay, vasculitic rash, urinary tract infection, recurrent abdominal pain, and a history of past renal disease are all indications for the evaluation for possible proteinuria (Hogg et al, 2000). In these circumstances it is prudent to thoroughly review the history and physical examination with an eye toward possible renal disease. Low to moderate levels of proteinuria, normal blood pressure, and the absence of hematuria, edema, or vasculitis are all reassuring. Values near normal on evaluation of serum creatinine may be reassuring but do not guarantee the absence of future worsening. In settings in which renal disease is suspected from history and examination, the suspected diagnosis should lead the evaluation process. The presence of associated edema, hypertension, and/or hematuria makes glomerular disease the most likely cause of proteinuria. Accurate quantitation of urinary protein and serum creatinine and electrolytes (including calcium and phosphorus), total protein and albumin, complement component C3, and streptococcal titers is needed. Quality renal ultrasonography will assess anatomy, size, and echogenicity. Nephrology evaluation may include additional serologic studies for rare diseases as indicated by the severity and form of illness.

BOX 123-2 Causes of Proteinuria

- Transient
 - Exercise
 - Fever
 - Stress/illness
- Orthostatic
- Drugs
 - Chemotherapy
 - Aminoglycosides
 - Heavy metal intoxication
- Tubular disease
 - Acute tubular necrosis
 - Interstitial nephritis
 - Cystic kidney diseases
 - Fanconi syndrome
 - Graft-versus-host disease
- Reflux nephropathy
- Glomerulonephritis: acute and chronic, all forms, including minimal change nephrotic syndrome
- Other chronic renal disease
 - Obstructive uropathy
 - Congenital renal dysplasia
 - Permanent residual dysfunction from acute disease (i.e., cortical necrosis, hemolytic uremic syndrome, glomerulonephritis)
- Diabetes mellitus
- Protein overload syndromes
 - Hemolysis
 - Rhabdomyolysis
 - Hypergammaglobulinemia

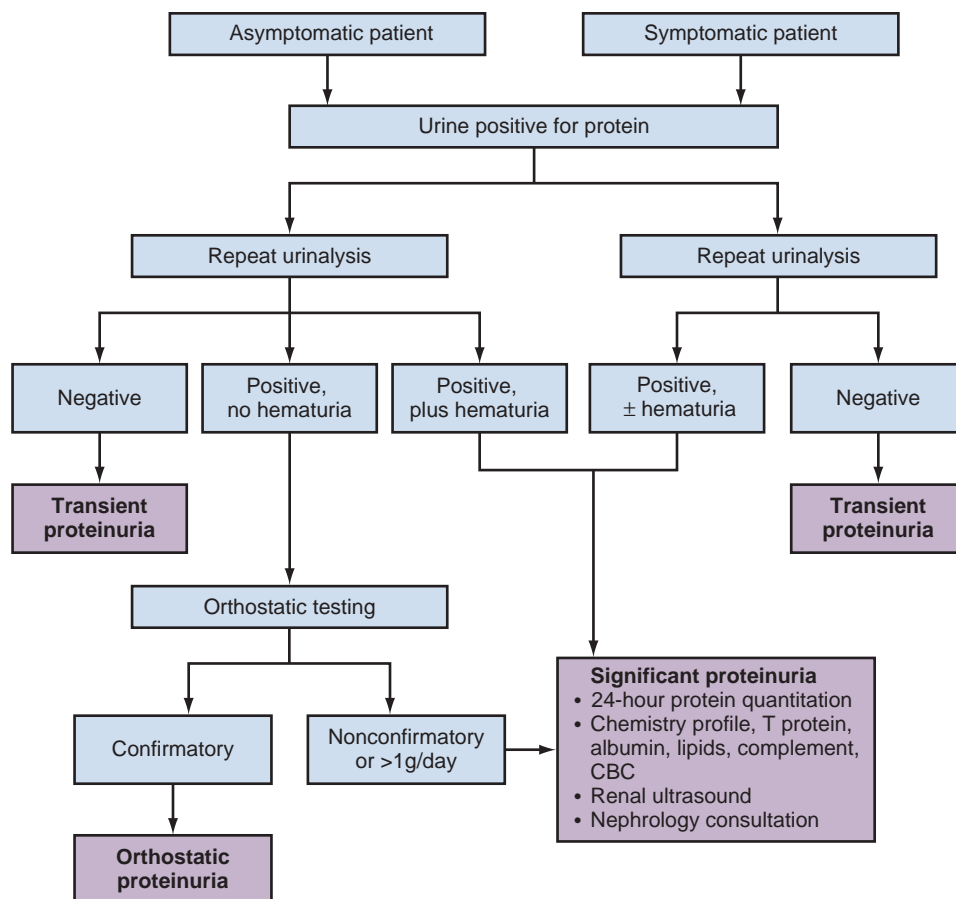

Figure 123-3. Evaluation of children with proteinuria. CBC, complete blood cell count.

Special mention should be made regarding the presentation and evaluation of proteinuria from reflux nephropathy. Reflux nephropathy may go undiagnosed for years and may present as asymptomatic proteinuria (commonly <1 g/day) with or without hypertension in the older child or adolescent. A careful history inquiring about past urinary tract infections or recurrent antibiotic use for fevers during early childhood may point to this diagnosis. Renal ultrasonography may be suggestive if renal asymmetry or parenchymal defects are seen but is insensitive in situations in which the scarred areas are small. Magnetic resonance imaging and nuclear imaging with a cortical agent such as dimercaptosuccinic acid (DMSA) are the most sensitive for diagnosis but more technically challenging in small children (McMahon et al, 2007). Voiding cystourethrography will be negative in a child whose reflux has resolved spontaneously and can be reserved for those in whom cortical imaging has confirmed scarring.

The time to refer a patient with proteinuria to a pediatric nephrologist depends upon the perceived severity of the underlying process, the comfort level of the treating physician, and the practical availability of nephrology services. The additional evaluations provided by a nephrologist will be dependent upon the suspected underlying process but may be expected to include more extensive biochemical testing such as complement assays and serologic studies for immune-mediated diseases, repeat quantitative urine studies for confirmation and trending, and specialized radiologic imaging. Percutaneous renal biopsy is usually needed for specific diagnosis and/or prognosis in cases of progressive or persistent glomerulonephritis.

Treatment

Transient proteinuria and orthostatic proteinuria are benign and do not require therapy. In acute or self-limited processes such as

AKI, postinfectious glomerulonephritis, or mild hemolytic uremic syndrome (HUS), proteinuria may persist for months following resolution of the primary disorder. Protein quantitation is usually of low degree (<1 g/24 hr or protein/creatinine ratio <1.0), should decline further with time, and does not require specific therapy. Worsening proteinuria is an indication for more detailed investigation.

In most circumstances of clinically important proteinuria, the treatment is directed toward cure or management of the primary disease, and changes in urinary protein excretion are often used as a marker of the success of treatment. Most acquired glomerular diseases are treated with immunomodulatory therapies such as corticosteroids, calcineurin inhibitors, cytotoxic drugs, or antibody therapies with varying degrees of success. Because many of these disorders are incurable or are only brought under control after permanent glomerular damage has occurred, the treatment of persistent proteinuria has become an additional option. Led by discoveries that showed benefits in renal life span in patients with nephropathy from type 1 diabetes mellitus (Cook et al, 1990), it is now routine practice to use angiotensin-converting enzyme inhibitors (ACEIs) and/or angiotensin II receptor blockers (ARBs) to decrease urinary protein excretion in patients with persistent high-grade glomerular proteinuria (>1 g/24 hr) (Webb et al, 2012). While not specifically proven effective in improving long-term renal outcomes in all forms of glomerular disease, especially in children, these agents clearly decrease urinary protein excretion by their hemodynamic effect of decreasing glomerular filtration pressure. Whether the long-term benefits are directly due to decreasing tubular protein or are secondary to reduction in the effects of hypertension so commonly associated with these disorders remains an area of debate. Likewise, the need for and efficacy of these agents in chronic low-grade proteinuria or purely tubular proteinuria remain unclear.

KEY POINTS: PROTEINURIA

- Asymptomatic, isolated proteinuria is a common finding on screening examinations and is usually transient.
- Persistent daily protein excretion greater than 150 mg/24 hr or a first-morning spot urine protein/creatinine ratio greater than 0.2 indicates the possibility of renal disease.
- The presence of hematuria, hypertension, edema, or systemic illness suggests glomerular disease and more urgent evaluation.
- Judicious treatment of chronic proteinuria with ACEIs can lower proteinuria and may lengthen renal life span.

Glomerular Disease

Whereas larger anatomic complications of the urinary tract are the most common issues managed by pediatric urologists, the pediatric nephrologist spends a significant portion of his or her practice addressing glomerular disease. While the pediatric urologist will not be expected to maintain expertise in the details of these disorders, it is quite appropriate to have a basic working understanding of their presentations, evaluations, and short-term prognoses since many children with any abnormalities in urinalysis will be first referred to a urologist.

The glomerular disorders may be transient or progressively damaging and the frequency of occurrence varies across the developmental spectrum of childhood and adolescence. Some progress very rapidly and others have more indolent courses and may present with incidental findings of hematuria and/or proteinuria in an otherwise healthy patient. While many disorders may be presumptively treated based on clinical features, renal biopsy remains the gold standard for diagnosis.

Over the years, much has been made of the differences and similarities of the numerous forms of “nephrotic syndrome” and “glomerulonephritis” with significant attempts to separate the two, but it is critical to understand that there are significant overlaps among the clinical presentations and outcomes of all of these disorders. The wise clinician utilizes clinical data, biopsy results, response to therapy, and clinical course to chart the expected course for any individual patient. **Classically, nephrotic syndrome is a clinical constellation including heavy proteinuria (for children defined as >40 mg/m²/hr), hypoalbuminemia (defined as albumin <2.5 g/dL), and edema, with or without hyperlipidemia.** Nephrotic syndrome may be genetically inherited, secondary to other illnesses, or a primary idiopathic process. These disorders appear to be due to acquired or congenital defects in the integrity of podocyte cytoskeletal structure and cell-cell interaction and are areas of intense research activity ([Grahammer et al, 2013](#)). Nephrotic syndrome may be isolated without evidence of “nephritis” or may be a significant component of any form of glomerulonephritis. **Glomerulonephritis is diagnosed in clinical scenarios in which there is evidence of glomerular inflammation as evidenced by the presence of hematuria, proteinuria, decreased GFR, and/or hypertension.** Glomerulonephritis may also be genetically inherited, secondary to other illnesses, or a primary idiopathic process. Given the breadth of the differential diagnoses possible, there is reason to narrow the field by making a few early investigations and then continuing the evaluation with a more narrowed focus.

Evaluation

Several simple assessments and questions can help narrow the differential diagnosis and assist in decision making regarding urgency of further evaluation:

1. *How old is the patient?* If less than 1 year of age, the ultimate process is most likely an inherited disorder. A number of glomerular diseases are more common in younger children while others cluster more commonly in adolescents ([Box 123-3](#)).

BOX 123-3 Common Age Ranges for Presentation of Glomerular Diseases**<1 YEAR**

Congenital infections

Diffuse mesangial sclerosis

Genetic diseases:

Congenital and infantile nephrotic syndromes

Denys-Drash and Frasier syndromes

1-10 YEARS

Postinfectious glomerulonephritis (GN)

Minimal change disease

Idiopathic focal segmental glomerulosclerosis (FSGS)

Henoch-Schönlein purpura

Hemolytic uremic syndrome

≥7 YEARS

Systemic lupus erythematosus

Systemic vasculitis

Idiopathic crescentic GN

Membranoproliferative GNs

Immunoglobulin A nephropathy

Idiopathic and secondary FSGS

Membranous nephropathy

Alport syndrome

Nail-patella syndrome

Pulmonary-renal syndromes

2. *Is this an acute issue or is there evidence of long-standing disease?* Many of these disorders have indolent presentations and may have been present silently for quite some time prior to diagnosis (Alport syndrome, secondary focal segmental glomerulosclerosis [FSGS]). Others are directly the result of an acute event (PSGN and HUS). Basic investigations such as hemoglobin, renal ultrasonography (are the kidneys large, indicating an acute process, or small, indicating a chronic progressive process?), and parathyroid hormone (PTH) (assessing for evidence of renal osteodystrophy) can be very helpful. It is important to note that **hypertension, hematuria, and edema can occur in any of these disorders and are not indicative of a specific diagnosis.**
3. *Has the patient had recurrent asymptomatic gross hematuria?* If so, immunoglobulin A (IgA) nephropathy, Alport syndrome, or thin basement membrane disease are most likely.
4. *Is there any evidence of extrarenal involvement?* While not always easily visible, evidence of skin disease, vasculitis, sinopulmonary disease, or other organ system involvement usually portends a systemic disorder of some type and often a more aggressive clinical course.
5. *Is significant hypertension or renal insufficiency present?* If yes, then advanced or aggressive disease is likely and emergent evaluation by the nephrology service is warranted.

Diagnosis and Management

The use of the above questions can help narrow the differential diagnosis significantly. Patients with significant edema and heavy proteinuria without evidence of multisystem involvement are most likely to have one of the disorders causing nephrotic syndrome. Patients with hypertension and milder edema are more likely to have a form of glomerulonephritis. Patients with rash or other organ system involvement are likely to have a systemic vasculitis or other systemic illness. Renal biopsy is often a critical component of diagnosis in all of these disorders, and with the advancement of genetic diagnoses, evaluations of uncommon presentations often include mutation analyses.

Nephrotic Syndrome in Infants. The distinction between “congenital” and “infantile” forms of nephrotic syndromes is somewhat vague because all of the disorders can be present at birth or may present later in infancy. Infants with congenital nephrotic syndrome of the Finnish type (CNF) are often edematous at birth or very shortly after, and may be diagnosed prenatally owing to very high elevations in maternal α -fetoprotein levels indicative of fetal proteinuria. These infants are commonly born prematurely and the placenta is usually significantly larger than normal. CNF is due to a homozygous mutation in the *NPISH1* gene (encoding nephrin) and affected infants classically have severe nephrotic syndrome with high risks of infection and thrombosis because of extreme protein loss (Jalanko, 2009). Congenital forms of FSGS usually present during the first year of life, with the most common being due to homozygous mutations of the *NPISH2* gene (encoding podocin) (Jalanko, 2009). Other genetic mutations known to result in lesions of focal sclerosis include disruptions in α -actinin 4 and CD2-associated protein (Jalanko, 2009). Mutations in the Wilms tumor suppressor gene *WT1* are associated with infantile nephrotic syndrome in Denys-Drash and Frasier syndromes, with the glomerular pathology showing diffuse mesangial sclerosis (Jalanko, 2009). While nephrotic syndrome in infancy is currently commonly found to be genetic in origin, it is important to remember that congenital infections and inflammations can also result in nephrotic syndrome. Cytomegalovirus, syphilis, rubella, hepatitis B, congenital SLE, toxoplasmosis, human immunodeficiency virus (HIV), and malaria are all known to cause nephrotic syndrome and should be considered in all early presentations of the disorder (Jalanko, 2009).

Nephrotic Syndrome in Older Children

Minimal Change Nephrotic Syndrome. The vast majority of children and adolescents with nephrotic syndrome have minimal change nephrotic syndrome (MCNS) (85% to 90% of preschoolers and 50% of adolescents), although the definitive diagnosis is often unknown because patients who respond to corticosteroids rarely undergo biopsy. The presentation is usually with the acute onset of dependent edema, often including ascites, in an otherwise well child, although an antecedent illness is also common. Most children are normotensive and have normal serum creatinine, although mild elevations may be seen with severe hypoalbuminemia resulting in intravascular volume depletion. Hyperlipidemia is common. Microscopic hematuria may be present but is minimal in quantity, and polarized examination of the urine will note oval fat bodies. The course of MCNS is one of remission with corticosteroids followed in two thirds of patients by intermittent relapses that may be occasional or frequent. Cytotoxic drugs (cyclophosphamide or chlorambucil) or calcineurin inhibitors (cyclosporine or tacrolimus) are used in patients with frequent relapses and steroid toxicities. The vast majority of patients with MCNS will “outgrow” the disorder by adolescence, and progression to renal insufficiency or end-stage renal disease (ESRD) is extremely uncommon, so much so as to question the diagnosis of minimal change disease. Patients with relapsed nephrotic syndrome are at risk for infection with encapsulated organisms and thrombosis owing to the loss of IgG and antithrombotic proteins. In addition, side effects of the treatment medications and the unpredictable nature of relapses add to the frustration experienced by caregivers despite the “minimal” risk of long-term sequelae of the disease. While patients with classic presentations and response to steroids will rarely undergo biopsy, the light microscopy findings are of normal kidney tissue (or at most mild focal increase in mesangial matrix or cellularity), negative immunofluorescence, and diffuse podocyte foot process effacement.

Focal Segmental Glomerulosclerosis. FSGS is the second most frequent cause of nephrotic syndrome in the pediatric age group, accounting for 10% to 20% of cases and increasing in frequency with age. FSGS has recently been subdivided into a number of pathologically distinct forms with variable prognostic outcomes (Schell and Huber, 2012). Its presentation is variable, with some patients presenting with classic nephrotic syndrome and others with heavy asymptomatic proteinuria with or without hypertension

and renal insufficiency. It is more common in African-Americans, is usually not completely or consistently responsive to steroids, and may be associated with evidence of tubular dysfunction, most commonly glycosuria and concentrating defects. Microhematuria is common. Renal biopsy findings classically note segmental glomerular sclerosis or capillary loop collapse in focal areas of the cortex, more prevalent in juxtamedullary nephrons. Evidence of tubulointerstitial damage is frequent. Immunofluorescence may detect immunoglobulin M (IgM) or C3 but not in large quantities, and electron microscopy confirms the sclerotic/atrophic lesions along with podocyte effacement. Patients with FSGS suffer complications of infection and thrombosis similar to those seen in MCNS, and these are ongoing risks given the long-term persistence of heavy proteinuria. Progression to CKD and ESRD is very common in patients who do not respond to steroids and may be rather rapid (within 5 to 7 years). The disease recurs in approximately 30% of renal transplant recipients and may lead to loss of the graft. High-dose corticosteroids, calcineurin inhibitors, cytotoxic agents, mycophenolate mofetil, and plasmapheresis have all been used as single agents or in combination with variable success. ACEIs and/or ARBs along with lipid-lowering agents are commonly used as adjunctive therapies to decrease the severity of proteinuria and long-term complications of hyperlipidemia. Growing understanding of podocyte molecular pathophysiology, biomarker signatures of disease, and phenotype-genotype correlations will hopefully continue to improve our ability to understand and manage the progressive nature of this challenging disorder.

Other Etiologies of Nephrotic Syndrome. Membranous nephropathy is rare in childhood, increasing to 10% to 20% of nephrotic syndrome diagnoses in adolescents. Membranous nephropathy may be idiopathic or may be secondary to SLE, hepatitis B, nephrotoxins, or malignancy. It cannot be clinically differentiated from other forms of nephrotic syndrome and requires renal biopsy for diagnosis. Spontaneous remission occurs in approximately one third of patients, with others developing slowly progressive CKD. The pathophysiology of the majority of cases of idiopathic membranous nephropathy has recently been determined to be attachment of circulating IgG₄ autoantibodies to the M-type phospholipase A₂ receptor 1 on podocytes (Beck and Salant, 2014). These antigen-antibody complexes bind complement within the glomerular basement membrane (GBM) and subsequently result in disruption of the slit diaphragm structures, causing proteinuria. The classic silver stain and electron microscopic biopsy findings of immune deposits surrounded by varying degrees of new extracellular matrix and GBM are a response to injury. Secondary forms of membranous nephropathy are caused by preformed circulating antigen-antibody complexes resulting in a similar injury pattern. The prognosis of membranous nephropathy is variable, with spontaneous resolution in about one third of patients and slow progression to ESRD in the remainder.

Membranoproliferative glomerulonephritis (MPGN) is also uncommon in childhood and is another disorder that has recently undergone serious reconsideration of nomenclature and classification because of growing understanding of the pathophysiology of the subtypes of the disorder (Bomback and Appel, 2012). Now known collectively as C3 glomerulopathies, these disorders are due to aberrant activation of the complement system. These disorders may present with classic nephrotic syndrome, features of progressive nephritis, or mixtures. Heavy proteinuria is common, significant micro- or macrohematuria is usual, and the majority of cases have low levels of complement component C3. Biopsy findings reveal mesangial hypercellularity, capillary proliferation, and mesangial cell interposition and duplication of GBM as a result of deposits of complement components and immunoglobulin. Subendothelial and mesangial deposits predominate in type I MPGN (in the old system) and the deposits typically contain immunoglobulin and complement. Type II MPGN (also referred to as dense deposit disease) is typified by intense GBM and mesangial electron-dense deposits that contain C3 alone. Mixed variants still defy definitive classification. The usual course of these diseases is

progression to ESRD despite therapies that typically include steroids and other immunomodulators. Recently, the use of eculizumab, a humanized antibody that prevents activation of the membrane attack complex, has brought promise as a potential targeted agent to halt the damage from chronic complement activation ([Bombback and Appel, 2012](#)).

Glomerulonephritis. There are several forms of glomerular disease in which the finding of “nephritis” usually predominates and the findings of nephrotic syndrome are less common. However, these disorders are quite heterogeneous in their presentations, and the astute clinician remains open to the complete spectrum of diagnoses until hard evidence is obtained.

Infection-Related Glomerulonephritis. The epidemiology of kidney inflammation associated with infection is undergoing significant change and the major types now may be referred to as “postinfectious glomerulonephritis” and “glomerulonephritis associated with active infection” ([Nadasdy and Hebert, 2011](#)). The incidence of PSGN is declining in developed countries because of changes in immunization practice and more effective antibiotic treatment of streptococcal disease, but the disease remains common in the developing world ([Eison et al, 2011](#)). Concomitantly, glomerulonephritis related to acute and chronic infections with *Staphylococcus aureus*, HIV, and hepatitis B/C is becoming more common.

PSGN classically develops 7 to 10 days following pharyngitis or cellulitis/impetigo caused by specific strains of group A *Streptococcus* and is characterized by gross hematuria (often described as “cola-colored” urine), subnephrotic-range proteinuria, hypertension with volume overload, low complement component C3, and positive antistreptolysin O and antideoxyribonuclease-B antibodies. Varying degrees of AKI are seen, including oligoanuria and the need for temporary dialysis. Historically 90% of patients recover “completely,” although with increasing understanding of the long-term risks of AKI from any cause, this estimate may be overly optimistic. Given the usual history and clinical diagnostic criteria for PSGN, few patients are currently biopsied but findings are expected to show marked glomerular cellular proliferation with infiltrating polymorphonuclear leukocytes, immunofluorescence positivity for C3 and IgG, and subepithelial electron-dense deposits in “humps.” The most acute phase of the disease lasts around 10 to 14 days but proteinuria and hematuria may linger for 6 months or so.

The glomerulonephritis of active infection differs from postinfectious disease in that it requires persistent infection and is most commonly seen in untreated or poorly treated deep or occult infections such as osteomyelitis, endocarditis, vascular shunts, or deep abscesses ([Nadasdy and Hebert, 2011](#)). This form of nephritis is also typified by chronic infection with HIV and hepatitis B/C, although biopsy findings differ. *Staphylococcus aureus*-associated glomerulonephritis is most commonly seen with methicillin-resistant strains and may be associated with evidence of vasculitis and purpura. It also mimics IgA nephropathy on biopsy, showing heavy IgA deposition but with the features of subepithelial and subendothelial immune complex deposition that are not seen in classic IgA disease. C3 is not usually low and, if abnormal, is usually minimally so. Given the frequency of purpura, this disorder should be considered at any time that a diagnosis of Henoch-Schönlein purpura (HSP) is considered. Given the risks of worsening underlying infection, steroids or other immunosuppressants are inappropriate treatment for *Staphylococcus aureus*-associated glomerulonephritis ([Nadasdy and Hebert, 2011](#)).

Immunoglobulin A Nephropathy. IgA nephropathy is the most common form of biopsy-proven glomerulonephritis in most of the world and affects both children and adults. The pathogenesis is linked to abnormalities in galactosylation of IgA₁ and may have both genetic and environmental components ([Hogg, 2010](#)). The course of the disease may be very mild, with diagnosis made only because of urinary screening findings of hematuria, or destructive disease resulting in glomerulosclerosis and ESRD. Presentations vary also from asymptomatic hematuria with or without proteinuria, to intermittent gross hematuria with intercurrent illnesses, to

more aggressive forms with gross hematuria, nephrotic syndrome, hypertension, and renal insufficiency. Biopsy findings include varying degrees of mesangial hypercellularity with increased mesangial matrix with or without glomerulosclerosis. Immunofluorescence findings of IgA deposition are required and may be associated with C3, IgG, and IgM staining as well. Electron-dense deposits are found in the mesangium. Most cases eventually resolve (although episodes of hematuria with illness may recur for years), but 20% of children will progress to renal failure, usually over a period of years. Clinical features of poor prognosis include severe proteinuria, renal insufficiency, and hypertension at the time of diagnosis and the finding of fibrosis or crescent formation of glomeruli on biopsy. Specific treatment is not available, and it is important to avoid potentially toxic therapies for patients unlikely to develop severe disease. Patients with mild disease may be treated with vitamin E and/or ACEIs. Those deemed high risk for progression commonly are treated with high-dose corticosteroids with or without additional immunosuppressant drugs such as azathioprine, cyclophosphamide, or mycophenolate mofetil, although none of the few small randomized controlled trials is sufficient to advocate for any specific regimen ([Hogg, 2010](#)).

Henoch-Schönlein Purpura. In contrast to IgA nephropathy, with which it shares renal biopsy similarities, HSP is a systemic leukocytoclastic vasculitis involving capillaries of the gastrointestinal tract, kidneys, skin, and/or joints resulting in a clinical syndrome of abdominal pain, nephritis, nonthrombocytopenic purpura (classically on the posterior legs and buttocks), and arthritis. Approximately 50% of children with HSP will develop evidence of nephritis within the first 4 to 6 weeks of diagnosis but most will have mild, self-limited disease. The symptoms may flare intermittently over months or even years, generally with consistently less severe manifestations. However, up to 15% of children with HSP nephritis will develop a progressive course resulting in ESRD ([Kawasaki, 2011](#)). These children most commonly have heavy proteinuria and evidence of renal insufficiency and hypertension early in the course of the disease. The renal biopsy findings of HSP are indistinguishable from those of IgA nephropathy and the pathogenesis is also linked to immune complexes containing galactose-deficient IgA₁ ([Kawasaki, 2011](#)). Corticosteroids are beneficial for treatment of arthritis, skin lesions, and abdominal pain but have not been proven to be beneficial for mild renal disease. Aggressive disease is commonly treated with high-dose corticosteroids with or without additional immunosuppressant agents and even plasmapheresis, but randomized controlled trials of sufficient power have not been done to prove efficacy.

Alport Syndrome (Hereditary Nephritis). Hereditary nephritis mimics IgA nephropathy in its presentation with intermittent gross hematuria with intercurrent illness. Persistent microscopic hematuria may precede the onset of proteinuria for some time, and progressive renal dysfunction develops over years. **The hereditary nephritides are a spectrum of disorders all of which are due to mutations in the type IV collagen genes that make up the GBM.** Alport syndrome is the most severe variant and is due to mutations in the α_5 subunit of type IV collagen on the X chromosome, thereby accounting for the X-linked inheritance pattern seen in 85% of cases. The remaining cases are due to mutations in α_3 and α_4 subunits of collagen IV and are inherited in autosomal recessive or autosomal dominant patterns ([Noone and Licht, 2013](#)). Classic Alport syndrome is associated with sensorineural hearing loss, anterior lenticonus, and leiomyomatosis, although the timing of extra-renal manifestations varies widely. With growing understanding of the mechanisms of podocyte and GBM interactions, genotype-phenotype correlations are beginning to explain the wide clinical spectrum seen in this disorder ([Noone and Licht, 2013](#)). Renal biopsy is diagnostic (although it may be challenging if done early in the course) and shows thinning and thickening of the GBM with splitting and lamellation of the lamina densa. Treatment of Alport syndrome is currently supportive, but blockade of the renin-angiotensin-aldosterone system has been shown to decrease proteinuria and delay renal failure ([Kashtan et al, 2013](#)).

Lupus Nephritis and Antineutrophil Cytoplasmic Antibody–Mediated Diseases

Lupus Nephritis. Although SLE is relatively uncommon in childhood, it is important to recognize that nephritis is more common and severe in childhood-onset SLE (Vachvanichsanong and McNeil, 2013). Most commonly, renal involvement with SLE is diagnosed during the evaluation for the nonrenal manifestations of the disease (including constitutional symptoms, rash, hematologic abnormalities, and arthritis), and significant hematuria, heavy proteinuria, abnormal creatinine, and hypertension are common. Around 80% of children diagnosed with SLE will have some form of renal involvement during the course of their disease. Renal biopsy should be considered for all children with SLE because the histopathology, together with clinical manifestations, dictates the most effective treatment approaches (Vachvanichsanong and McNeil, 2013).

The most recent classification system of lupus nephritis (Weening et al, 2004) can be simplified into six categories: Class I—minimal mesangial (normal glomeruli), Class II—mesangial proliferative, Class III—focal endocapillary proliferative, Class IV—diffuse endocapillary proliferative, Class V—membranous, and Class VI—advanced sclerosing. Class IV nephritis is typically the most severe with the highest likelihood of progression to ESRD, but repeat biopsies are often indicated if the clinical course does not match the pathology of an earlier biopsy. Treatment of lupus nephritis is based on biopsy classification and disease severity but usually includes induction with high-dose corticosteroids and cytotoxic agents (usually cyclophosphamide), although mycophenolate is now used as induction therapy in many cases. Maintenance therapy with other immunosuppressive drugs such as calcineurin inhibitors and rituximab is also used. Long-term patient and renal survival now approximates 90% in Caucasian adults (Moroni et al, 2013), although the success rates in children seem to be a bit lower.

Antineutrophil Cytoplasmic Antibody (ANCA)–Associated and ANCA-like Vasculitis. Systemic vasculitis caused by antineutrophil cytoplasmic antibodies (ANCAs) is fortunately very rare in childhood. Granulomatosis with polyangiitis (formerly known as Wegener disease), microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (formerly known as Churg-Strauss syndrome) make up this group of disorders that are characterized by inflammation of small and medium-sized arteries in multiple organs, most commonly in the upper and lower respiratory tract and kidneys (Twilt and Benseler, 2014). Granulomatosis with polyangiitis is associated with cANCA—antibodies against proteinase 3 found in the cytoplasm of neutrophils. Microscopic polyangiitis is associated with pANCA—antibodies against myeloperoxidase. Eosinophilic granulomatosis with polyangiitis is not routinely associated with ANCAs but instead with significant eosinophilia. However, its clinical course and treatments are similar to ANCA-associated diseases. These disorders commonly present with a history of upper and lower respiratory tract complaints and diffuse constitutional symptoms such as fatigue, weight loss, and malaise, and the renal disease may be diagnosed incidentally at the time of a “sick visit.” Kidney involvement is seen in approximately 80% to 90% of children affected. Hematuria and proteinuria are the hallmarks, with rapidly progressive glomerulonephritis and hypertension common pictures. Renal biopsy shows necrotizing crescentic pauci-immune nephritis, usually severe. Final diagnosis is usually determined on the basis of ANCA results. Treatment usually consists of a high-dose corticosteroid and cyclophosphamide. The adjunctive use of rituximab and plasmapheresis has become more common, especially in cases with dialysis dependence and/or pulmonary hemorrhage, but few long-term data exist on which to base therapeutic decisions, especially in children, so most approaches mimic current treatments for adults.

Thrombotic Microangiopathies. Thrombotic microangiopathy (TMA) (Trachtman, 2013) is characterized by the clinical findings of microangiopathic hemolytic anemia, thrombocytopenia, and kidney injury manifesting as varying degrees of hematuria, proteinuria, and decreased GFR. “Typical” HUS caused by infections with Shiga toxin–producing *Escherichia coli* (STEC-HUS) is a common cause of AKI in previously healthy children, and accounts for

approximately 90% of all TMA in childhood. “Atypical” forms of HUS may be acquired from infection (most commonly *Streptococcus pneumoniae*) or medication or may be familial (caused by functional abnormalities of the complement cascade). Pneumococcal HUS is usually quite severe and occurs concomitantly with invasive pneumococcal disease such as meningitis, sepsis, or pneumonia, and is more common in very young children. Thrombotic thrombocytopenic purpura (TTP) occurs as a result of defective processing of endothelial von Willebrand factor multimers from ADAMTS13 dysfunction, and is also quite rare.

Patients with STEC-HUS typically present with varying degrees of diffuse endothelial injury, including evidence of renal dysfunction, pancreatitis, respiratory distress syndrome, central nervous system dysfunction (including seizures, mental status changes, hemorrhage, and hemiparesis), liver failure, cardiac dysfunction, and/or intestinal ischemia. Symptoms develop days following an episode of hemorrhagic colitis. Laboratory findings show hemolytic anemia, thrombocytopenia, and evidence of renal dysfunction (hematuria, proteinuria, and decreased GFR) as well as other organ system biomarkers. The pathogenesis of STEC-HUS is due to gastrointestinal absorption of the Shiga toxin, binding of the toxin to endothelial cells, and subsequent inhibition of protein synthesis and cell damage. The damage to the endothelial cells activates the coagulation cascade, and activation of platelets results in microthrombi. Additional inflammation and complement activation likely add to the damage. Treatment of STEC-HUS is supportive with careful management of fluid and electrolyte balance, anemia, renal failure, and other organ system dysfunction as needed. Forty percent to 50% of patients will require dialysis.

Recent advances in the understanding of complement regulatory proteins have led to the discovery of multiple mutations and complexes of mutations that result in the rare familial forms of atypical HUS (Noris et al, 2012). It is likely that functional variations in complement control also impact the phenotype of TMAs induced by other mechanisms. Abnormalities in factor H, factor I, factor B, membrane cofactor protein, and C3 have been the most commonly detected, with most patients having only one mutation. The pattern of familial HUS is one of repeated episodes, commonly occurring after relatively mild upper respiratory infections and fairly rapid progression to ESRD. Interestingly, the process may not present until adulthood, highlighting the likelihood of environmental triggers superimposing onto a genetic susceptibility to cause disease. Treatment of previously undiagnosed atypical HUS usually includes plasma infusion with or without plasmapheresis. Eculizumab, a monoclonal antibody against complement component C5, acts by preventing the formation of the membrane attack complex as the final step in cell destruction. This drug is now considered standard of care when the diagnosis is confirmed, although the frequency of use remains controversial (Trachtman, 2013). Historically, prognosis for these disorders is quite poor, with most patients succumbing to CKD or other complications, including frequent recurrence following transplantation. It is hoped that eculizumab will improve the course for these patients.

Patients who develop atypical HUS but do not have familial forms present a quandary for nephrologists. Some have been found to have transient antibodies to complement proteins, some are taking medications that may be inciting (by unclear mechanisms), and others appear to be truly sporadic. The outcomes for these patients are not as severe as those who have familial disorders, and treatment remains controversial.

TTP is quite uncommon in childhood and, when seen, is most likely to be associated with SLE, although it can be spontaneous or associated with medications. The final common TMA pathway for this disorder is initiated by abnormalities in function of ADAMTS13. This protein should degrade ultralarge multimers of von Willebrand factor in order to halt platelet activation and the development of thrombi. ADAMTS13 activity can be suppressed as a result of genetic mutation or by autoimmune processes. Clinically, TTP mimics atypical HUS with the exception that diffuse neurologic abnormalities are frequent. TTP is effectively treated with plasmapheresis in most cases (Trachtman, 2013).

KEY POINTS: GLOMERULAR DISEASE

- Glomerular disorders are manifested by evidence of proteinuria with or without hematuria and with or without evidence of inflammation (decreased GFR, hypertension).
- Nephrotic syndrome is defined as edema, heavy proteinuria ($>40 \text{ mg/m}^2/\text{hr}$), hypoalbuminemia ($<2.5 \text{ g/dL}$), and hyperlipidemia. It may be present as an isolated disorder or as a part of any renal inflammatory disease.
- Minimal change disease and its associated nephrotic syndrome is the most common glomerular disorder in childhood and is a presumptive diagnosis in the absence of evidence of inflammatory disease. Its response to steroids and relapsing course assist in diagnosis.
- FSGS is poorly responsive to steroids and is likely to progress to ESRD over time.
- Acute PSGN presents with gross hematuria (classically described as “cola-colored”) following infection. Hypertension and mild decreases in GFR are common, but most patients recover without detectable sequelae.
- IgA nephropathy is also common and often presents as intermittent gross hematuria with or without proteinuria following intercurrent illness. Nephrotic-range proteinuria or abnormal GFR is indicative of poor long-term outcome.
- Renal biopsy is often needed for definitive diagnosis of glomerular disorders and determination of prognosis and appropriate treatment.
- Molecular genetics is dramatically changing our understanding of the pathogenesis of many glomerular diseases and may direct future treatment strategies to more effective targets.

Tubular Disorders

The role of the renal tubule is to refine the glomerular filtrate by reabsorption or secretion of solutes and ultimately create the urinary contents appropriate for physiologic homeostasis. The efficacy of the tubule as a reabsorptive organ can be best appreciated by recalling that normal GFR ($100 \text{ mL/min/1.73 m}^2$) results in an astounding 144 liters of filtrate entering the proximal tubule daily while only approximately 1% of that exits as urine. **The proximal tubule is responsible for the bulk of reabsorption, hence its high energy requirements and susceptibility to ischemia.** Sodium, chloride, glucose, phosphorus, low-MW proteins, bicarbonate, organic acids, and water are all transported across the proximal tubule while the loop of Henle transports sodium, potassium, chloride, and calcium. More distal parts of the nephron fine-tune sodium, chloride, calcium, magnesium, potassium, proton, and water content. The majority of these processes are driven in some way by active transport, usually by ATP-dependent activity of the basolateral Na^+/K^+ -ATPase. The sophistication of the tubular architecture and cellular arrangement is immense, and all parts of the nephron are able, under normal circumstances, to compensate for transient derangements in function in another area. However, chronic dysfunction of any transport system is not usually completely correctable by other mechanisms. Disorders of the tubule may be inherited or acquired (most commonly as a result of damage from ischemia or medication), may be transient or permanent, and may be specific for one molecule or more generalized. Clinical presentations commonly include failure to thrive, polyuria, and polydipsia.

Proximal Tubule Disorders

Fanconi Syndrome. Fanconi syndrome is the result of generalized proximal tubule dysfunction and is defined by tubular wasting of bicarbonate, phosphorus, amino acids, and glucose. It occurs as a result of inherited genetic defects, from heavy metal toxicity, and from a number of chemotherapeutic agents, most commonly ifosfamide and platinum derivatives. The diagnosis is made using

serum and urine electrolyte results that confirm wasting of the compounds mentioned earlier. Once the diagnosis of Fanconi syndrome is made, the search for the cause of the tubular disorder must begin.

The most common inherited disorder that results in Fanconi syndrome is *nephropathic cystinosis*, a disorder that was in fact first described by Fanconi himself (Nesterova and Gahl, 2013). Other causes of Fanconi syndrome include galactosemia, glycogen storage diseases, tyrosinemia, and other rare disorders. Cystinosis is a rare autosomal recessive disorder characterized by aberrant accumulation of cystine within lysosomes as a result of mutations in the *CTNS* (cystinosis) gene. While cystine crystal deposition occurs in most tissues, the proximal tubule is exquisitely sensitive, although it remains controversial as to whether the mechanism is through direct toxicity, aberrant energy production, or apoptosis. The severe form of the disease presents early in childhood with growth failure and electrolyte abnormalities that direct the evaluation toward Fanconi syndrome. Nephrocalcinosis and hypothyroidism are not uncommon, and corneal crystals are usually present on slit-lamp examination before 2 years of age. Carnitine malabsorption is also problematic. Definitive diagnosis is the finding of elevated white cell cystine levels with confirmation of specific molecular mutations by genetic testing. Renal function is normal early in the course but if untreated will decline, and progression to ESRD continues to occur even after effective treatment with cystine-depleting medications. Treatment of cystinosis includes management of the renal wasting of electrolytes as well as specific cystine-depleting therapy. Treatment of the Fanconi syndrome includes bicarbonate or citrate therapy (often at high doses because of wasting), as well as potassium, phosphorus, vitamin D, and thyroxine supplementation as needed. Close attention to nutrition is required, and many children will require a gastrostomy tube in order to provide adequate fluid, calories, and medications. Cystine-depleting therapy with cysteamine is of proven benefit in suppressing damage caused by cystine accumulation (Gahl et al, 2007). The drug acts by entering the lysosome and reacting with cystine to form a disulfide that can be transported from the lysosome. Early, adherent, and long-term treatment is necessary to maintain efficacy.

Proximal Renal Tubular Acidosis. Under normal circumstances the proximal tubule reabsorbs essentially all filtered bicarbonate. However, dysfunction in carbonic anhydrase or other transport proteins related to bicarbonate reabsorption will result in bicarbonate loss into the urine until a new steady state is reached at a lower serum bicarbonate concentration. When the level of filtered bicarbonate drops to the level of reabsorptive capacity, urinary bicarbonate loss ceases and urine pH remains low because of distal secretion of metabolic protons. Proximal RTA is a common feature of Fanconi syndrome but may also be isolated. It is quite common in premature infants and may persist for some months in older infants. Resolution in these cases is thought to be due to delayed maturation of bicarbonate transport mechanisms. Children with proximal RTA usually have growth failure, polyuria, and hypokalemia from acidosis-driven K^+ secretion. Treatment requires frequent high doses of citrate or bicarbonate along with potassium supplementation.

Dent Disease. Dent disease is another tubulopathy for which recent research has provided significant understanding (Chadha and Alon, 2009). Now recognized as clinically and genetically heterogeneous, Dent disease classically presents as an X-linked recessive disorder resulting in low-MW proteinuria, hypercalciuria, nephrocalcinosis and/or nephrolithiasis, and progressive renal failure. Patients may have additional tubular wasting of other electrolytes and meet full criteria for Fanconi syndrome. The disorder is due to inactivating mutations of the *CLCN5* gene that encodes the ClC-5 voltage-gated chloride channel. The exact mechanisms by which abnormalities in this channel result in the varied electrolyte disarrays seen in Dent disease remain unclear. Recently mutations in the *OCRL1* gene (responsible for Lowe syndrome, another cause of Fanconi syndrome) have been found in patients with Dent disease. Because this gene encodes a protein that controls cell membrane transport via lipid modification, the complexity of this spectrum of disorders can be expected to keep investigators busy for

some time. There is no specific treatment for Dent disease, and therapy centers on the management of stones and the complications of progressive CKD.

Hypophosphatemic Rickets. Hypophosphatemic rickets may occur as a result of a number of inherited or acquired abnormalities in the proximal tubular handling of phosphorus (Penido and Alon, 2014). Because the end result of these abnormalities is abnormal bone mineralization, the clinical picture of rickets includes widening of metaphyses of long bones, prominence of the costochondral junction, and genu valgum/varus after weight bearing begins. X-linked hypophosphatemia is the most common inherited form of rickets. It usually manifests clinical symptoms within the first 2 years of life, with males being more severely affected while the disease varies from asymptomatic hyperphosphaturia to severe disease in females. The *PHEX* gene that encodes a cell surface membrane-bound endopeptidase is mutated in many kindreds with this disorder. *PHEX* mutations are associated with high circulating levels of fibroblast growth factor-23 (FGF-23), a hormone that inhibits renal phosphate reabsorption and vitamin D production, but the exact mechanisms linking the mutated enzyme to FGF-23 and the final phenotypic changes remain unclear. Evaluation of suspected hypophosphatemic rickets should include radiologic bone studies, serum and urine calcium and phosphorus determinations (including calculation of the tubular reabsorption of phosphate; normal is >85%), and serum PTH, FGF-23, and vitamin D levels. Given the growing number of identifiable forms of hypophosphatemic rickets, it is appropriate to consult with a nephrologist and/or endocrinologist for current genetic testing options and to appropriately focus therapy. At this point, the mainstay of therapy for X-linked hypophosphatemia is supplementation with calcitriol and phosphorus, although the development of nephrocalcinosis and CKD may occur. Treatments focused on FGF-23 are currently in development.

Primary Renal Glucosuria. Primary renal glucosuria is a benign condition but one that frequently results in specialty referrals because of fears of diabetes mellitus. This "disorder" is most commonly found on routine urinalysis and is *not* associated with polyuria, polydipsia, hyperglycemia, or any other tubular dysfunction. The glucose leak is caused by a mutation in the proximal tubular Na⁺-glucose transporter gene *SGLT2*, and is inherited in an autosomal recessive fashion. The abnormality does not predispose to any disease state and does not require therapy.

Distal Tubule and Collecting Duct Disorders

Bartter Syndrome. Recent research efforts have elucidated a number of mechanisms responsible for Bartter syndrome (Chadha and Alon, 2009). Appearing as one would expect to see with chronic loop diuretic use, this autosomal recessive disorder is characterized by hypokalemic alkalosis, renal salt wasting, hypercalciuria, and hyperreninemic hyperaldosteronism with normal blood pressure. A number of phenotypes linked with a variety of mutations have now been described. The severe antenatal form is associated with polyhydramnios, preterm delivery, severe neonatal fluid and electrolyte disarray, and early-onset nephrocalcinosis while the classic variant is milder and often presents with growth delay, motor weakness, and milder metabolic disturbances. All forms are the result of aberrant epithelial transport of Na⁺ and Cl⁻ across the thick ascending limb of the loop of Henle. The antenatal form of the disease is caused by mutations in the gene for the furosemide-sensitive Na⁺,K⁺,2Cl⁻ cotransporter (NKCC2) responsible for high-quantity sodium, potassium, and chloride reabsorption. A milder form of the disease is caused by a mutation in the renal outer medullary potassium channel responsible for maintaining luminal K⁺ concentrations adequate for NKCC2 activity. Several additional phenotypes have been recently described, all with mutations in a variety of proteins and transporters ultimately responsible for chloride transport. Diagnosis of these disorders is based on clinical suspicion and supportive metabolic studies, and finally genetic sequencing. Treatment remains supportive, primarily with potassium chloride supplementation, often in combination with potassium-sparing

diuretics and drugs that slightly decrease GFR (ACEIs and nonsteroidal anti-inflammatory drugs [NSAIDs]) in order to decrease the filtered load of chloride. Long-term consequences of nephrocalcinosis and hypokalemia may result in progressive CKD.

Distal Renal Tubular Acidosis. Distal renal tubular acidosis (also known as type 1 RTA) results from abnormal H⁺ ion secretion in the distal nephron. As with proximal RTA, distal RTA is characterized by a normal anion gap hyperchloremic metabolic acidosis and is commonly detected either because of family history or during an evaluation for failure to thrive. These patients may be differentiated from those with proximal RTA by the presence of hypercalciuria and a persistently elevated urine pH. Over time these patients often develop stubborn stone disease. Treatment is by provision of base equivalent to normal distal proton secretion (usually no greater than 3 mEq/kg/day) along with potassium supplementation. While clearly a heritable disorder in many cases and given a number of likely target transporters and enzymes, genetic diagnosis of distal RTA remains elusive.

Type 4 RTA is distal RTA with hyperkalemia and is most commonly seen associated with obstructive uropathy, interstitial disease, or multicystic dysplasia. In these cases the pathophysiology results from impaired response to mineralocorticoid caused by damage to the cortical collecting duct. In rarer circumstances, true mineralocorticoid deficiency may be present or chronic medications may be causative. Hyperkalemia is usually out of proportion to the degree of renal insufficiency. Treatment is by replacement of needed base, but as a sodium salt alone given the hyperkalemia. Appropriate management of obstructive uropathy is warranted, but the persistence of chronic developmental damage makes significant improvement in the resistance to mineralocorticoid unlikely.

Gitelman Syndrome. Gitelman syndrome is an autosomal recessive disorder that on the surface looks much like Bartter syndrome, with hypokalemic alkalosis and renal salt wasting. However, the phenotype is much milder and most children present later in childhood without significant failure to thrive. Laboratory evaluation for Gitelman syndrome differs from that for Bartter syndrome by very low urinary calcium excretion and the presence of hypermagnesuria with hypomagnesemia, which may lead to tetany or weakness. The molecular defect in Gitelman syndrome is most commonly a mutation in the thiazide-sensitive electroneutral Na⁺,Cl⁻ cotransporter gene (*NCCT*). The hypocalciuria and hypermagnesuria are secondary effects of volume contraction and downregulation of the apical magnesium channel (Chadha and Alon, 2009). Treatment is with potassium and magnesium supplementation; amiloride is a common adjunctive therapy acting to spare both potassium and magnesium wasting.

Nephrogenic Diabetes Insipidus. Nephrogenic diabetes insipidus (NDI) is defined as collecting duct insensitivity to arginine vasopressin and may occur as a result of medications (most commonly lithium) or structural renal disease. In these cases the severity of water loss is relatively mild. However, inherited forms of NDI may be clinically dramatic, presenting with recurrent severe hypernatremic dehydration in the neonatal period, often with seizures. Developmental delays may occur owing to repeated episodes of hypernatremia, and failure to thrive is common because of the greater desire to ingest water rather than nutrients. Over time, the extremely high volume of urine output may result in hydronephrosis. Definitive diagnosis of NDI (and differentiation from central diabetes insipidus) is made using a water deprivation test. Baseline weight and urine and plasma osmolalities should be obtained, followed by withholding of fluids. Urine volume should be quantitated and weight checked every 1 to 2 hours. Urine osmolality should be checked hourly. At any point that weight loss is 3% or greater, a serum osmolality test should be done and an intravenous dose of vasopressin administered. Urine output should be observed and urine and serum osmolalities checked 60 minutes after the vasopressin dose, and access to fluids should be returned at that point. Patients with central diabetes insipidus will respond to vasopressin by decreasing their urine output, increasing urine osmolality, and decreasing serum osmolality. Patients with NDI will have no response. Infants should have this testing performed under

direct medical observation in order to avoid the risk of rapid and severe dehydration that can occur if weight loss is not accurately monitored or fluids are not reintroduced quickly when warranted.

The most common molecular defect causing NDI is a mutation in the arginine vasopressin receptor-2 gene (*AVPR2*) located on the basolateral side of collecting duct principal cells. In the absence of normal vasopressin signaling, aquaporin-2 (*AQP2*) trafficking is impaired, resulting in lack of appropriate *AQP2* activity to maintain normal water reabsorption (Wesche et al, 2012). This form of NDI is therefore inherited in an X-linked fashion. More uncommonly seen (around 10% of patients with NDI) are autosomal dominant or recessive mutations in the *AQP2* gene that also result in *AQP2* trafficking abnormalities as opposed to structural abnormalities in the water channel itself. Treatment of NDI centers on provision of adequate free water and calories with attempts to decrease the renal solute load by limiting protein and sodium. Adjunctive therapies with NSAIDs (to decrease GFR) or thiazide diuretics (to cause gentle sodium loss resulting in enhanced proximal salt and water reabsorption) may be needed in extremely polyuric infants. As infants mature and are able to clearly express thirst and then obtain fluids independently, the episodes of dehydration become less severe.

Pseudohypoaldosteronism Type I and Liddle Syndrome. These two very rare abnormalities are worthy of mention as examples of cortical collecting duct abnormalities. They also have a “yin-yang” relationship, with pseudohypoaldosteronism type I (PHA-I) being a phenotype of aldosterone resistance and Liddle syndrome a phenotype of apparent aldosterone excess. Two separate gene defects may be seen with mutations in the apical epithelial sodium channel (*ENaC*) subunits or in the mineralocorticoid receptor. PHA-I results from loss-of-function mutations in either gene while Liddle syndrome results from gain-of-function mutations in either gene (Chadha and Alon, 2009).

PHA-I presents in infancy, often very early and very dramatically, with polyuria, dehydration and profound hyponatremia, hyperkalemia, and acidosis that are commonly life threatening. The differential diagnosis includes salt-wasting adrenal insufficiencies (which are more common) with the differentiating fact that corticosteroids and mineralocorticoid therapies do *not* correct the electrolyte disarray. Treatment is with sodium chloride supplementation (often as saline to provide additional volume support) and potassium restriction or exchange resins. Sodium bicarbonate may also be needed to help with acidosis and management of hyponatremia and hyperkalemia. With time and the ability for the child to access salt and fluid independently, the risk of life-threatening electrolyte disarray decreases. Liddle syndrome is characterized by hypokalemic alkalosis and severe hypertension resulting from uncontrolled sodium reabsorption in the collecting duct. The hypokalemia and alkalosis are due to the requisite secretion of potassium and protons that occurs as a part of sodium exchange. Patients with Liddle syndrome are treated with amiloride or triamterene, which are direct *ENaC* inhibitors.

KEY POINTS: TUBULAR DISORDERS

- Polydipsia, polyuria, and poor growth are common features of renal tubular disorders.
- Type 4 RTA resulting from obstructive uropathy is the most common “tubulopathy” in pediatric patients.
- Evaluation of the tubular disorders should include evaluation of urinary sodium, potassium, calcium, magnesium, glucose, amino acids, uric acid, and phosphorus along with complementary serum studies as indicated by the suspected diagnosis.
- With the exception of patients with known obstructive uropathy, the finding of hydronephrosis in tubular disorders is most commonly due to long-standing polyuria.
- Determination of acid-base status may be a clue to diagnosis as a number of tubular disorders result in systemic acidosis or systemic alkalosis.

Nephrolithiasis

Epidemiology

Urinary tract stones in children have been recognized for centuries, yet we remain limited in our knowledge of modern trends of incidence, recurrence risk, and optimal management. The incidence is clearly increasing in the United States and has been estimated to be above 50 per 100,000 adolescents (Tasian and Copelovitch, 2014), up from 18 per 100,000 in 1989 (Stapleton, 1989). The causes of this increase remain undefined, although changing diets and lifestyle as well as obesity have been implicated (Jackson, 2014). The types of stones in some areas are changing as well, with a globalization of stone type distribution (Dator, 2010). This is manifest in the reduced frequency of uric acid and ammonium acid urate stones in developing countries, being replaced by a more Western distribution of predominantly calcium stones. The incidence of struvite stones in children has decreased significantly and presently represents about 10% to 20% of stones, in contrast to a reported 60% in pediatric studies from 1958 to 1985 (Diamond, 1991).

While many stones can be attributed to specific medical conditions, some with significant systemic medical implications, the majority must be considered idiopathic. Metabolic factors such as hypercalciuria or hypocitraturia can be associated with the occurrence of stones in children, but their relevance to the risk of recurrence and to defining the value of specific therapy remains tenuous.

Clinical Presentation

The clinical presentation of pediatric nephrolithiasis is distinct from that in adults, with fewer children having classic renal colic but instead often presenting in more subtle ways or being diagnosed by incidental detection. Approximately 60% of children will present with pain, including both abdominal and flank, 30% with hematuria, and 15% with dysuria. Asymptomatic presentation accounts for approximately 15% (Valentini and Lakshmanan, 2011). It should be kept in mind that stones in children may be associated with infection and fever as well as failure to thrive, and have been misinterpreted as appendicitis (Polito et al, 2009). In cases of recurrent abdominal pain, imaging will usually be undertaken and will usually, but not always, reveal the cause as a calculus.

The pattern of clinical presentation will define the urgency and modality of therapy, particularly when fever is present. The obstructing stone in the setting of possible urinary infection is an emergency.

Etiology

Stone formation in children is similar to that in adults, and the detailed description of stone formation in Chapter 52 is relevant to children as well. Particular types of stone formation, however, are seen specifically in children, and the potential for associated metabolic conditions that have systemic implications must be considered in any child with nephrolithiasis. Some of these conditions, such as primary hyperoxaluria, are more effectively treated with earlier diagnosis. Determining the underlying cause and initiating appropriate therapy permits reduced morbidity from recurrence as well as potential extraurinary manifestations.

The clinical context can aid in defining etiology. Overt structural defects of the urinary tract (e.g., obstruction with hydronephrosis), neuropathic bladder dysfunction, or recurrent urinary tract infections can suggest likely causes. Non-urinary tract disease (e.g., inflammatory bowel disease), prematurity (furosemide-induced nephrocalcinosis), steroid usage, known genetic abnormalities, and malignancy can also suggest a likely cause.

In the presentation of a first-time, isolated stone, the most readily available information will be whether the stone is radiopaque or radiolucent. In some cases the density can be estimated by Hounsfield units when computed tomography has been performed. Metabolic evaluation, which also provides the stone composition, is

usually deferred until after stone removal. In the event of smaller stones for which intervention is not immediately needed, basic evaluation can be undertaken.

Hypercalciuria is the most common metabolic cause of renal stones in children and, while most often idiopathic, can be associated with specific renal and systemic abnormalities. Systemic conditions include hypercalcemia resulting from hyperparathyroidism, which in turn may be due to several clinical syndromes. These include primary hyperparathyroidism as well as hyperparathyroidism in association with multiple endocrine neoplasia type 1 (MEN-1); a high index of suspicion for MEN-1 should be entertained in a child with hyperparathyroidism and stones (Romero Arenas et al, 2014). Recurrent stones, especially if associated with bone disease, should trigger an evaluation for hyperparathyroidism (Bhadada et al, 2008). Hypercalciuria with normal serum calcium levels is due to either excessive absorption of calcium from the gut (absorptive hypercalciuria) or renal leak in which urinary calcium is poorly reabsorbed in the tubules, leading to urinary supersaturation. Abnormal phosphate reabsorption can also be the basis for stone formation, although rarely.

RTA, most commonly type 1 (distal), is an important cause of nephrolithiasis in children. Approximately 70% of affected patients with type 1 RTA will have stones and about half are diagnosed through the initial presentation with stone. RTA is an inability to excrete hydrogen ions, leading to alkaline urine (and systemic acidosis). In children this can lead to failure to thrive, vomiting, or diarrhea. Calcium phosphate stones are most common. These patients have hypercalciuria, hypocitraturia, and alkaline urine pH; the hypercalciuria is further aggravated by acidosis-induced bone demineralization causing secondary hyperparathyroidism.

Hypocitraturia can be a significant contributing factor in stone formation. Citrate acts to reduce calcium crystallization through several mechanisms. The calcium/citrate ratio is considered a more useful indicator of stone risk than simply the concentration of citrate (Penido et al, 2013). The clinical importance of hypocitraturia lies in its being readily corrected with oral administration of citrate-containing drinks.

Children with severe seizure disorders are often treated with ketogenic diets, producing systemic acidosis leading to hypercalciuria and hypocitraturia (Sampath et al, 2007). Several anticonvulsants contribute to metabolic predisposition to stone formation, including topiramate and zonisamide.

Gastrointestinal diseases can be associated with nephrolithiasis, often as a result of chelating of intestinal calcium, which frees oxalate to be absorbed and subsequently excreted in the urine. The chelation of calcium is associated with steatorrhea, as in cystic fibrosis and inflammatory bowel disease.

Primary hyperoxaluria usually presents before the age of 6, often with multiple stones, and is associated with progressive renal failure and frequently recurring calcium oxalate stones. Primary hyperoxaluria type 1 (PH1) is due to deficiency in alanine:glyoxalate aminotransferase and can only be cured with liver transplantation, often combined with renal transplantation because of the chronic renal damage occurring from calcium oxalate deposition. Primary hyperoxaluria type 2 (PH2) is due to deficiency in glyoxylate reductase/D-glycerate dehydrogenase, which produces high levels of excretion of L-glyceric acid and oxalate.

Cystinuria is an X-linked inherited renal tubular defect of the reabsorption of four amino acids: cystine, ornithine, lysine, and arginine (COLA) (Claes and Jackson, 2012). Only cystine is insoluble as a dimer of two cysteine molecules joined by sulfide bonds. The cysteine molecules are much more soluble than cystine, an important factor in therapy using sulfide bond dissociation. These stones are usually radiopaque and are very hard, making lithotripsy difficult.

Dent disease produces nephrocalcinosis, proteinuria, renal dysfunction, and rickets as well as nephrolithiasis.

Another X-linked disorder associated with nephrolithiasis is Lesch-Nyhan syndrome, a defect in purine metabolism that produces uric acid stones. The clinical context is notable with mental retardation, self-mutilation, hyperuricemia, and premature gout.

Management consists of vigorous hydration, reduced purine intake, allopurinol, and urinary alkalinization.

Evaluation

An initial stone presenting in a child should prompt a formal metabolic evaluation. While this is not standard practice for all adults, the purpose in the child is to identify the few yet significant potential underlying systemic illnesses that can present with stone disease, as well as to identify those children at presumably higher risk of recurrence.

Initial evaluation is largely through imaging and seeks to define the stone location and burden, presence of any associated anatomic abnormalities or urinary obstruction, and possibly stone type based on radiolucency. Basic metabolic parameters should be obtained initially, including serum electrolytes, serum calcium and phosphate, and urinalysis with microscopic examination. Urinalysis should include the specific gravity, as an indication of hydration, and pH. Urinalysis should focus on the presence of pyuria and crystalluria. The appearance of crystals can be diagnostic for specific types of stone disease, including uric acid, cystine, and struvite stones. A spot urinary calcium/creatinine ratio can be useful as a baseline to identify very abnormal levels of urinary calcium.

Following stone removal, a formal metabolic evaluation can be undertaken to more precisely define the likely etiology and recurrence risk (Pietrow et al, 2002). Repeat serum studies should be performed, particularly if initial studies were borderline abnormal. A formal 24-hour urine collection should be attempted but may be very difficult in younger children. In those cases, a timed collection may be the best option, or the clinician may elect to use spot collections for calcium, oxalate, and citrate, indexed to creatinine level and calcium/citrate ratio. There are several commercial services that will perform stone risk profiles, yet the normal parameters for children are not well established and not specifically tied to recurrence risk. The impact of age on normal levels, particularly of calcium excretion, must be considered. Calcium excretion in the urine is very high in the newborn and gradually decreases through childhood. Urinary calcium/creatinine ratios in the newborn are as high as 0.50 but are less than 0.20 by early childhood.

Recurrence risk is of course a key clinical factor and is difficult to define. A rate of about 16% was noted in earlier studies (Diamond, 1991), and a rate of about 19% more recently (Pietrow et al, 2002). These authors demonstrated a higher recurrence rate in children with identified metabolic abnormalities. When variable follow-up was factored, a rate of 0.32 per patient-year was reported (Tekin et al, 2002). This study also demonstrated a reduction in recurrence risk with oral citrate therapy.

Medical Management

Immediate management of any child presenting with a possible stone consists in relieving obstruction when this may be associated with infection. Obstruction otherwise is usually partial and management is directed toward pain control and facilitation of stone passage. If high-grade obstruction is suggested, early decompression is indicated. Typically, the degree of hydronephrosis will be a rough indicator of the severity and acuity of obstruction, but this is not always so. In very acute stone-induced obstruction, the degree of dilation may be mild. In such cases functional imaging will reveal a delayed nephrogram pattern either on computed tomography, diuretic renography, or intravenous pyelography. Acute surgical management is discussed in Chapter 135 but will usually include percutaneous antegrade diversion or retrograde ureteral stenting.

Further facilitation of stone passage is based on vigorous hydration and medical management. Medical management can be as simple as NSAIDs to control pain and relax the ureteral smooth muscle, but may require drainage or definitive stone removal.

α -Blockade is used to more aggressively reduce ureteral smooth muscle tone to permit more rapid stone passage. While the results of various series are diverse, a formal literature review does suggest some value in these agents. Children showed a 55% passage rate of

ureteral stones in contrast to 44% in untreated children (Tasian et al, 2014). Although some series have suggested that stones pass more slowly in children, it has been our experience that proportionally larger stones will pass more readily in children than in adults. For this reason a period of watchful waiting in a minimally symptomatic child is a logical approach.

Once the stone has passed, the focus of therapy is prevention of further episodes and inhibition of any new stone growth. For all stone types the foundation of prevention is to reduce the concentration of lithogenic salts and create as nonlithogenic a urinary environment as possible. The first goal includes reducing the urinary excretion of lithogenic salts, particularly calcium and oxalate, as well as increasing urinary volume, which has the same effect. The second goal includes adjusting the urinary pH to limit crystal precipitation and to increase the concentration of inhibitors of crystallization, such as citrate. Reducing the lithogenic concentration is both direct by reducing the dietary content of calcium and oxalate, and indirect by reducing calcium secretion by the kidneys. Most importantly, this includes reducing dietary sodium intake (Escrignano et al, 2014). This reduces urinary calcium excretion because sodium and calcium are secreted through similar cellular ion channels. Indeed, it has been shown that reducing sodium intake is preferable to and more effective than reducing calcium intake in the prevention of nephrolithiasis. In more refractory cases, direct potassium citrate therapy may be of value. In children this is always difficult to define because there is no clear end point to therapy. Oral treatment with potassium citrate is effective in increasing urinary citrate levels and reducing calcium excretion and crystallization (Tasian and Copelovitch, 2014).

The use of medication to reduce stone formation in children is a challenging area in which to define best practices. In the recurrent stone former, the use of thiazide diuretics has the effect of limiting recurrent calcium nephrolithiasis, yet poses the question of the appropriate duration of therapy and what indicators can be used to define when reduction or discontinuation may be attempted. In our practice the use of thiazides is limited to those children with recurrent stone formation or growth as well as demonstrable hypercalciuria refractory to hydration and dietary interventions. Standard doses for diuresis are started but then may be reduced to a point that maintains a normal urine calcium level. Long-term compliance can be an issue, and the effects of long-term therapy are not well defined. Concerns for potassium wasting and hypocalciuria must be considered in use of thiazides.

In special situations, such as cystinuria, medical therapy is much more clearly defined. The principle of treatment in cystinuria is to reduce the concentration of urinary cystine to less than 300 mg/L (Pak, 1983) by creation of alkaline urine and the use of a cystine-binding agent to create a mixed cystine-drug disulfide bond to increase solubility. This can be accomplished by several agents, including D-penicillamine, α -mercaptopyrionylglycine (tiopronin [Thiola]), and captopril (Claes and Jackson, 2012). The first of these agents is associated with significant side effects, limiting its utility considerably. Medical management of cystinuria remains a major challenge, even with available medical agents, and the need for surgical intervention remains high.

PH1 is also amenable to specific medical management, although this is at best a temporizing solution (Cochar and Rumsby, 2013). Ultimately kidney and liver transplantation appears to be the definitive therapy. To limit stone recurrence and the impact of some forms of systemic oxalosis, pyridoxine is used starting at 5 mg/kg/day and titrated to a maximum of 20 mg/kg/day using urinary oxalate excretion as the end point (Hoyer-Kuhn et al, 2014). The target is a decrease of 30% or more. Potassium citrate at 0.10 to 0.15 mg/kg/day is also used to limit the risk of nephrolithiasis by alkalinizing the urine to a pH of 6.2 to 6.8. Vigorous hydration is, as with all other types of nephrolithiasis, an essential foundation for medical therapy.

Hypertension

For children and adolescents, hypertension is defined as blood pressure consistently greater than the 95th percentile for age, sex,

KEY POINTS: NEPHROLITHIASIS

- Approximately 60% of children will present with pain, including both abdominal and flank, 30% with hematuria, and 15% with dysuria.
- The incidence of struvite stones in children has decreased significantly, and presently represents about 10% to 20% of stones, in contrast to a reported 60% in studies of children from 1958 to 1985.
- Stone etiology may be suggested by the presence of non-urinary tract disease, such as inflammatory bowel disease, prematurity (furosemide-induced nephrocalcinosis), steroid usage, known genetic abnormalities, and malignancy.
- Initial evaluation is largely through imaging and seeks to define the stone location and burden, presence of any associated anatomic abnormalities, urinary obstruction, and possibly stone type based on radiolucency.
- Metabolic evaluation is recommended in all children presenting with stone but is usually deferred until after stone removal, which also provides the stone composition. In the event of smaller stones for which intervention is not immediately needed, basic evaluation can be undertaken.
- Hypercalciuria is the most common metabolic cause of renal stones in children and, while most often idiopathic, can be associated with specific renal and systemic abnormalities.
- RTA is an important cause of nephrolithiasis in children, most commonly type 1 (distal) RTA. Approximately 70% of affected patients with type 1 RTA will have stones and about half are diagnosed through the initial presentation with stone. RTA is an inability to excrete hydrogen ions, leading to alkaline urine (and systemic acidosis).
- Primary hyperoxaluria usually presents before the age of 6, often with multiple stones, and is associated with progressive renal failure and frequently recurring calcium oxalate stones.
- Cystinuria is an X-linked inherited renal tubular defect of the reabsorption of the four amino acids cystine, ornithine, lysine, and arginine (COLA).
- Recurrence risk is a key clinical factor but is difficult to define. In earlier studies, a rate of about 16% was noted in contrast to about 19% more recently.
- Immediate management of any child presenting with a possible stone consists in relieving obstruction when this may be associated with infection. Obstruction otherwise is usually partial and management is directed toward pain control and facilitation of stone passage.

and height with normal blood pressure continuously increasing from birth to adulthood (Table 123-2). Depending on the setting, the prevalence of hypertension in children is estimated at 1% to 4.5% and is clearly increasing, most predominantly as a result of the obesity epidemic affecting the young (Lande and Kupferman, 2014). In the past, the pediatric nephrologist was the “hypertension specialist” for children because the most common causes of hypertension were renal in origin. While the etiologies have shifted to metabolic syndrome in most age groups, the nephrologist continues to play a major role in the evaluation and management of childhood hypertension, especially the complex and severe hypertension often seen in children with kidney disease. Given the prevalence of childhood obesity (with approximately 25% to 35% of U.S. children classified as overweight or obese) it is critical that all physicians treating children encourage healthy nutrition and exercise regimens. Extensive searches for other etiologies of hypertension are not always warranted, but the astute physician will recognize that children with secondary causes of hypertension may also be overweight, and carefully consider an individualized approach to evaluation to maximize the likelihood that the cause of high blood pressure is appropriately attributed and managed.

TABLE 123-2 Pediatric Definitions of Hypertension

Normal	SBP or DBP <90th percentile for age and gender
Prehypertensive	SBP or DBP from 90th to <95th percentile or BP >120/80 mm Hg even if <90th percentile up to 95th percentile
Stage 1 hypertension	SBP or DBP 95th to 99th percentile + 5 mm Hg
Stage 2 hypertension	SBP or DBP >99th percentile + 5 mm Hg

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

In cooperative older children, blood pressure should be measured in a calm environment with the child in a sitting position with the arm resting comfortably at heart level. Blood pressure assessments in infants are usually obtained in the arm with the child supine and commonly require multiple measurements until consistent values are obtained. The appropriate-sized cuff is one that covers at least two thirds of the distance between the olecranon and the acromion, and the bladder should encircle the arm.

Unfortunately, there have been no further updates on the definitions of hypertension in children since the fourth report of the [National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents \(2004\)](#), and currently there are no plans to update that report. The tables in that report, stratified by age, sex, and height, therefore remain the standard for defining hypertension and its differing stages. These normative data are derived from auscultatory measurements, while recommendations suggest that 24-hour blood pressure monitoring with oscillometric measurements are most appropriate for diagnosis of hypertension, even though the two methods give different readings. From a practical clinical perspective in a pediatric urology practice, many children will have clear hypertension that will require ongoing medication management that is most commonly handled by the nephrology service. Patients with borderline readings in the urology settings may comfortably be referred to nephrology for the evaluations noted later and further decision making. Of most importance is that consistent, careful, and technically appropriate blood pressure measurements be made on essentially all children in the pediatric urology clinic so that suitable referrals may be made as needed.

While primary hypertension is now quite prevalent in the pediatric age group, renal parenchymal and renovascular disorders remain the most common causes of secondary hypertension, accounting for more than 75% of cases ([Brady and Feld, 2009](#)). The most common causes to be encountered in a pediatric urology practice will be obstructive uropathies (most frequently ureteropelvic junction and posterior urethral valve obstructions), reflux nephropathy, and chronic parenchymal disease of almost any form, including cystic diseases. In these instances, hypertension may be severe, even in the youngest of neonates ([Flynn, 2012](#)). On occasion, patients with acute glomerulonephritis or HUS will be referred to a urologist because of gross hematuria, and hypertension may be noted as a significant clinical finding. **It should be remembered that immobilization (commonly following severe trauma) and skeletal traction can result in hypertension, especially in teen males.** Given its increasing frequency, primary hypertension will be seen in the pediatric urology clinic, is found in all ethnic groups, and is usually asymptomatic. These patients will most commonly be overweight, have a positive family history of hypertension, and have hypertensive responses to stressful events. Inactivity and sleep apnea are also commonly associated. Even the child with apparent straightforward enuresis could have upper tract disease,

thereby serving as a reminder that essentially *all* children in a urology practice should have their blood pressures measured.

In the absence of identified urinary tract abnormalities, evaluation for an etiology for childhood hypertension is most logically carried out in the pediatric nephrology or cardiology environment. After confirmation of abnormal blood pressure, recommended workup includes a minimum of urinalysis, complete serum biochemical profile, renal ultrasonography, and echocardiogram. As mentioned earlier, 24-hour ambulatory blood pressure monitoring is becoming more frequently utilized and is especially helpful when masked hypertension or white-coat hypertension is a possible diagnosis ([Flynn and Urbina, 2012](#)). Additional studies as indicated by history and clinical picture may include plasma renin and aldosterone, thyroid studies, plasma cortisol, urinary catecholamines, and renal arteriography (reserved for severe hypertension with suspicion of renovascular disease). Genetic testing for the rare single-gene defects causing hypertension (Liddle syndrome, apparent mineralocorticoid excess, and glucocorticoid-remediable aldosteronism) is now available but, given costs, should be reserved for cases in which there is evidence for one of these disorders (early severe hypertension, hypokalemic alkalosis, and/or suppressed plasma renin) ([Brady and Feld, 2009](#)).

Severe acute hypertension, while uncommon, requires emergent treatment, often with parenteral therapy (nicardipine being currently in favor). While avoided in adult practice, oral nifedipine is still used in severe pediatric hypertension without significant concern for cardiac ischemia, most commonly as an initial therapy while awaiting intravenous access and drug delivery. The goal of emergent therapy is to lower the mean blood pressure by 20% to 30% to avoid end-organ damage from hypertension without compromising blood flow.

The treatment of chronic pediatric hypertension is most commonly focused on the etiology of the elevated blood pressure. Primary, or essential, hypertension may be addressed with lifestyle modification, including exercise, weight loss, sodium restriction, and smoking cessation, as long as there is no evidence of end-organ involvement (most commonly left ventricular hypertrophy). If lifestyle modifications have not resulted in change in 3 to 6 months, pharmacologic therapy is warranted. For those patients in whom lifestyle modifications are not welcomed, pharmacologic therapy may best be started earlier. Patients with renal/urinary tract etiologies of their hypertension are most commonly treated with ACEIs or ARBs. While very effective in controlling blood pressure from angiotensin-mediated causes, there is risk of AKI from loss of renal autoregulation in states of dehydration, and patients must be counseled to contact their physicians or hold medications when dehydration is suspected or likely. The other risk of ACEI/ARB therapy is the teratogenic effects of these medications when taken during pregnancy. It is critical that prescribing physicians carefully instruct patients and families about these potential serious side effects when choosing therapy. Calcium channel blockers (most commonly amlodipine) are also commonly used, especially if abnormal renal function limits ACEI/ARB use. β -Adrenergic blockers (atenolol, metoprolol) and mixed α - and β -blockers (labetalol) may be used as well. Clonidine is also quite effective, especially in circumstances in which central nervous system involvement in the hypertension is suspected. Essentially all classes of antihypertensives used in adults are used and are effective in children, and progress has been made by regulatory incentives for randomized, controlled studies of new agents in children. It is unlikely that many older agents will ever be appropriately studied in children, but many have long clinical practice track records that provide guidance to the careful practitioner ([Blowey, 2012](#)). Goals of chronic therapy are blood pressures less than the 90th percentile for age, sex, and height, and many advocate for lower levels for children with chronic heart and/or kidney disease.

Acute Kidney Injury

AKI is defined as an abrupt loss of homeostatic capability that includes but is not limited to acute renal "failure." Over the last

KEY POINTS: HYPERTENSION

- Hypertension is defined as blood pressure greater than the 95th percentile for age, sex, and height.
- Proper technique, equipment, and patient cooperation are vital in measuring accurate blood pressure in children.
- Primary hypertension is now the most common cause of hypertension in childhood and is strongly linked to obesity, inactivity, and poor nutrition.
- Evaluation for hypertension should include consideration of renal causes as well as family history and lifestyle issues.
- Echocardiography is an important component of evaluation because left ventricular hypertrophy is common in pediatric hypertension (approximately 40%).
- With careful attention to dosing and strategic approaches designed to address the likely cause of hypertension, many drug regimens will be effective in controlling blood pressure in children of all ages.

TABLE 123-3 KDIGO Criteria for Acute Kidney Injury

STAGE	SERUM CREATININE (SCr) CHANGES	URINE OUTPUT CHANGES
I	SCr increase ≥ 0.3 mg/dL in 48 hr or 1.5-1.9 times baseline	< 0.5 mL/kg/hr for 6-12 hr
II	SCr increase 2.0-2.9 times baseline	< 0.5 mL/kg/hr for 12 hr
III	SCr ≥ 3.0 increase or SCr > 4.0 mg/dL or If < 18 yr of age, estimated creatinine clearance < 35 mL/min/1.73 m ²	< 0.5 mL/kg/hr for 24 hr or < 0.3 mL/kg/hr for 12 hr

Modified from Kellum JA, Lameire N; KDIGO AKI Guideline Work Group. Diagnosis, evaluation, and management of acute kidney injury: a KDIGO summary (Pt. 1). *Crit Care* 2013;17:204.

decade, the recognition of renal compromise as an epidemiologic risk factor for patient morbidity and mortality has helped lead a change in terminology that allows for categorical definitions of acute renal dysfunction instead of the past binary definitions that were never standardized. In 2005 the Acute Dialysis Quality Initiative developed a multidimensional stratification system for AKI called RIFLE (for risk, injury, failure, loss, and ESRD) using graded criteria for changes in GFR and changes in urine output in order to define AKI. This approach recognized the often-independent changes in serum creatinine levels and urine volume in the various settings and etiologies leading to functional insufficiency. This initial stratification strategy has since been utilized by several different groups to define a lower threshold, remove the end-stage outcomes (in order to focus on areas that might be treatable), provide modifications that are useful in pediatrics (Fortenberry et al, 2013), and harmonize the various approaches. While a number of these strategies are still in use in research, the most recent consensus criteria are those from the *Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group (2012)* (Table 123-3).

Etiology and Evaluation

The etiologies of AKI also have been changing in the last decades in the developed world. The most common causes (Box 123-4) have shifted from primary renal diseases such as acute glomerulonephritis and HUS to secondary effects of systemic illness or its treatment (sepsis, ischemia, complications of complex surgi-

BOX 123-4 Causes of Acute Kidney Injury

Decreased true intravascular volume

- Third-space losses: sepsis, trauma, burns, nephrotic syndrome
- Gastrointestinal losses
- Salt wasting: renal or adrenal
- Diabetes insipidus: central or renal

Decreased apparent intravascular volume: congestive heart failure

Acute tubular necrosis/cortical necrosis

- Hypoxic-ischemic insults
- Medications: aminoglycosides, intravenous contrast agents, nonsteroidal anti-inflammatory drugs, chemotherapeutics
- Exogenous toxins: ethylene glycol, methanol
- Endogenous toxins: hemoglobin, myoglobin

Tumor lysis syndrome and uric acid nephropathy

Interstitial nephritis

- Medication induced: anticonvulsants, antibiotics
- Idiopathic

Glomerulonephritis: all causes

Vascular disorders

- Hemolytic uremic syndrome
- Renal artery or vein thrombosis

Infection

- Pyelonephritis
- Sepsis

Obstructive lesions

- Obstructed single kidney
- Bilateral ureteral obstruction
- Urethral obstruction

cal procedures such as congenital heart disease repair). However, the pediatric urologist may become involved with patients with any of these disorders and should be prepared to aid the team in investigating possible causes for acute declines in kidney function. It is also important to note that, while necessary to thinking and planning for therapy, the past concepts of “prerenal” versus “intrinsic” versus “postrenal” classifications are less critical. For example, the differentiation between oliguria and increased creatinine caused by decreased perfusion pressure compared to that caused by intrinsic tubular necrosis is difficult, especially in the complex intensive care unit environment. It is also apparent that not all regions of the kidney are evenly involved in the progression of AKI. Therefore it is best to make a diagnosis of AKI and recognize the risks and approaches to that determination than be mired in borderline laboratory results complicated by time and medications. Likewise, in most critically ill children the causes of AKI are likely to be multiple, and the astute clinician will consider all of them as potential targets for improvement. Obstructive lesions (congenital or acquired) may often present a picture of “acute-on-chronic” dysfunction with worsening of function owing to infection, edema, or postoperative surgical problems. This being said, assessment of renal function beyond change in creatinine and recent urine output may be reasonable, especially when considering effective renal perfusion. As shown in Table 123-4, decreased perfusion in the absence of tubular damage may be differentiated from established necrotic injury using a combination of urinary concentrating ability, urine solute characteristics, and urinalysis. Fractional excretion of urea (and with less sensitivity and specificity, fractional excretion of uric acid) is most useful in the setting of active diuretic use, which obviously alters the ability of sodium excretion to mark the presence of impaired tubular function (Diskin et al, 2010).

The advances in pediatric critical care practice have created an environment for enhanced understanding of the pathophysiology

TABLE 123-4 Urine Studies and Results for Differentiation of Renal Damage from Underperfusion

TEST	RENAL HYPOPERFUSION	ESTABLISHED DAMAGE
BUN/creatinine ratio	>20	<20
Urine specific gravity	>1.020	≈1.010
Urine osmolality	>350	≈300
Urine sodium	<20 mEq/L	>30 mEq/L
Fractional excretion of sodium	<1%	>2%
Fractional excretion of urea	<35%	>50%
Fractional excretion of uric acid	<12%	>20%
Urine microscopy	Normal ± hyaline casts	Proteinuria, cellular casts (type depending on primary etiology), eosinophils (interstitial nephritis)

BUN, blood urea nitrogen.

and treatment options for children with AKI. With improved diagnostic criteria, it is estimated that between 12% and 70% of high-risk neonates develop AKI (Carmody and Charlton, 2013) and that around 10% of all children admitted to a pediatric intensive care unit develop AKI, with that number rising to around 80% in the most seriously ill (Devarajan, 2011). It is now recognized that AKI is an independent risk factor for mortality in children (Fortenberry et al, 2013) and that fluid overload is an additional independent risk for mortality (Foland et al, 2004).

It is important to recognize that AKI is an evolving process with damage occurring at different rates and with varying severity over time, in different parts of the kidney, and in response to new noxious events. Changes do not occur in stepwise fashion: serum creatinine increases continuously, urine sediment increases over time, ultrasonography may reveal normal kidneys (but usually with no baseline for renal volume or echogenicity), renal blood flow is rarely examined directly, and biopsies are very rarely performed for AKI in children. For all these reasons, the severity of damage is often unclear and management defaults to preserving remaining function, avoidance of additional insults, supportive care, and watchful waiting. The outcomes of AKI are not as benign as previously believed. Of pediatric survivors of AKI in a large tertiary referral center (where the most common causes of AKI were complications of congenital heart surgery, neonatal care, and marrow and solid organ transplantation), 10% developed ESRD in the 3 to 5 years after discharge and 60% had evidence of renal damage (microalbuminuria, hyperfiltration, decreased GFR, or hypertension) over the same timeframe (Askenazi et al, 2006). These results indicate a need for ongoing follow-up of children with AKI and better strategies for maintenance of renal health for this at-risk population.

Management of AKI remains problematic and largely supportive, although recent research discoveries of new biomarkers of early AKI may help identify new therapeutic targets and allow earlier detection and protective strategies. Furosemide and “renal dose” dopamine have been shown *not* to be effective in improving outcomes, although urine output may increase and maintenance of effective perfusion pressure is essential. Likewise, *N*-acetylcysteine, fluids, sodium bicarbonate, statins, fenoldopam, and theophylline have all failed to show consistent benefits as treatment options. Hopefully, improved diagnosis, including the use of early and more specific biomarkers, and better understanding of the bimodal effects of some treatments (e.g., too little fluid resuscitation is clearly harmful, excessive fluid is also deleterious) may allow highly focused therapies that may improve outcomes.

Management

Current treatment strategies should include restoration of adequate renal blood flow and avoidance of nephrotoxic drugs. Fluids should be given to restore intravascular volume with the reminder that aggressive fluid administration without careful attention to cardiovascular responses risks the morbidity and mortality induced by fluid overload—risks that appear with as little as 10% excess fluid (Foland et al, 2004). Hypertension may occur in a number of cases

of AKI and is likely to be the result of fluid overload as well as intrinsic renal responses. Care to determine fluid balance is needed to appropriately direct therapy, and ACEIs, while effective in lowering blood pressure, may actually worsen renal compromise by further decreasing effective GFR. Hyponatremia is common with AKI, most usually from iatrogenic fluid overload with hypotonic fluid. Hyperkalemia develops from decreased filtration, acidosis, tissue damage, and catabolism. Acidosis develops from impaired secretion of normal acid production, increased acid production resulting from ischemia and catabolism, and compromise of respiratory compensation in the critically ill. Hypocalcemia and hyperphosphatemia are also common and require attention to nutritional support.

In extremely critically ill children, continuous renal replacement therapy (CRRT) most commonly by continuous venovenous hemofiltration has become increasingly utilized, although peritoneal dialysis (PD) and intermittent hemodialysis (HD) are still used. Modality choice is most often based on center experience and preference (Sutherland et al, 2014).

KEY POINTS: ACUTE KIDNEY INJURY

- AKI is defined as the inability of the kidneys to acutely regulate fluids and electrolytes because of a sudden drop in GFR.
- AKI is common in critically ill children and results in increased acute morbidity and mortality as well as long-term risks for CKD.
- Creatinine and blood urea nitrogen are insensitive markers of AKI. New and better options for diagnosis of early AKI are in development.
- Changes in serum creatinine and severity of oliguria are the center of new staging criteria for AKI.
- Treatment of AKI remains largely supportive, but dialysis therapies for even the smallest children are increasingly used with growing technical success.

Chronic Kidney Disease

CKD is a state of irreversible kidney damage that remains stable or progresses to ESRD over time. After years of increase from 1990 to 2003, the incidence of children initiating renal replacement therapy in the United States has decreased slightly with 1161 children beginning ESRD treatment in 2012, representing around 15 new ESRD patients per 1 million children. This contrasts with approximately 115,000 new ESRD patients in the adult population (350 per 1 million population). Approximately 7500 children were receiving dialysis or had functioning renal transplants in 2012 (United States Renal Data System, 2014c). The incidence and prevalence of pediatric CKD less severe than ESRD are not known. Given the shortened life span of children on dialysis and the growing shortage of organs available for transplantation, early detection and improved management of CKD are crucial in order to prevent or improve grave outcomes.

TABLE 123-5 Classification of Chronic Kidney Disease for Children Older than Age 2 Years

STAGE	DEFINITION	GFR (mL/min/1.73 m ²)
1	Normal or ↓ GFR (with kidney damage)	≥90
2	Mild ↓ GFR (with kidney damage)	60-89
3	Moderate ↓ GFR	30-59
4	Severe ↓ GFR	15-29
5	Kidney failure	<15 or dialysis

GFR, glomerular filtration rate.

Etiology

The causes of CKD and ESRD in children are quite different than those in adults, with approximately 36% of cases resulting from cystic/hereditary/congenital disorders and 22% from glomerular disease (contrasted with nearly half resulting from diabetes and another third from hypertension in adults) (United States Renal Data System, 2014a). In 2002 the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) outlined a classification system for CKD that has since become widely accepted (Table 123-5). It is important to note that this classification does not officially apply to children less than 2 years of age who have not yet reached normal renal functional maturity, and the system applies to patients with kidney disease for greater than 3 months. Stages 1 and 2 require evidence of kidney damage, defined as structural (on biopsy) or functional (proteinuria, hypertension, or abnormal imaging). Higher stages are classified by GFR measurements alone. Recent work from the CKiD (CKD in Children) Study has modified the previously used Schwartz equation to better estimate GFR in children using both creatinine and cystatin C (Schwartz et al, 2009), although the standard Schwartz equation— $\text{GFR (mL/min/1.73 m}^2\text{)} = 0.413 \times \text{height (cm)}/\text{serum creatinine (mg/dL)}$ —remains in use in common clinical practice.

CKD in children is associated with proteinuria of varying degrees, hypertension, acidosis, electrolyte disorders, renal osteodystrophy, dyslipidemia, anemia, growth failure, uremia, neurocognitive delays, and decreased quality of life, with each of these unfortunate effects adding needs for pharmacologic support, nutritional supplementation, and strategies to maximize normal development. The psychosocial impacts of CKD on the family are significant. In the case of congenital anatomic disorders, intervention should be considered to ensure regular voiding, maintain adequate drainage of the urinary tract, and prevent infection. Medical management can delay the development and effects of metabolic disarray but is rarely effective in halting the process completely (Wong et al, 2012; Mas-sengill and Ferris, 2014).

Medical Complications of Chronic Kidney Disease

The proteinuria of CKD may be low grade or nephrotic range, with severity directly correlated in most diseases with speed of decline in GFR. The use of ACEIs/ARBs is common to decrease hyperfiltration of remaining nephrons, suppress renal fibrosis, and slow progressive decline in GFR. The effectiveness of this approach appears to vary with the etiology of the disease process, but most clinicians attempt use of renin-angiotensin blockade to blunt the inexorable declines expected with CKD.

Children with cystic dysplasia, obstructive uropathies, and tubulopathies exhibit disrupted renal concentrating capacity and may require sodium and water supplementation and special attention during times of acute illness that risk dehydration. In contrast, children with chronic glomerulonephritis may need salt and water restriction to prevent edema and hypertension.

Hypokalemia occurs in children with tubulopathies and requires potassium supplementation, while children with obstructive uropa-

thies and advanced CKD usually require potassium restriction and/or removal.

Progressive acidosis is common in children with CKD, with the development of an anion gap acidosis owing to reduced excretion of the organic and inorganic acids produced as a result of normal metabolism. If uncorrected, chronic acidosis results in retardation of linear growth as well as decreased bone mineralization. Oral alkali therapy (with bicarbonate, acetate, or citrate) corrects the abnormalities.

Renal osteodystrophy results from abnormalities of calcium, phosphorus, and vitamin D that occur in CKD and result in rickets, osteopenia, secondary hyperparathyroidism, and growth failure along with other bone disturbances. Treatment requires suppression of PTH by supplementation with vitamin D analogues, calcium supplementation and phosphorus restriction, and/or the use of oral phosphate binders. Aluminum salts are no longer used because of complications of neurotoxicity with long-term use.

Anemia is nearly universal as CKD progresses and is commonly due to reduced renal production of erythropoietin, iron deficiency, or both. However, chronic inflammation (most commonly associated with diseases such as SLE or other immune-mediated glomerulonephritides) and hyperparathyroidism also contribute. Treatment requires restoration of normal iron stores and parenteral (commonly subcutaneous) erythropoiesis-stimulating agents. Both short-acting recombinant erythropoietin and longer-acting glycosylated forms are in current use.

Poor appetite, limited food options, and oromotor dysfunction all contribute to impaired nutrition and poor linear growth. Infants with advanced CKD commonly require enteral tube feedings in order to achieve the necessary caloric intake for growth and often develop oral aversions that may require significant therapy to improve. However, growth delay is closely associated with neurocognitive delays in development, and aggressive maintenance of necessary nutrition is imperative for long-term outcomes. Enteral feeding may be used at night in order to maintain normal social eating behavior patterns while supplementing needed calories for growth. Protein restriction is *not* recommended. Short stature results from poor nutrition, renal osteodystrophy, electrolyte imbalance, and derangements in the growth hormone–insulin-like growth factor-1 axis. Once adequate caloric intake is established, treatment with recombinant human growth hormone is indicated if the height standard deviation score is less than –2. Unfortunately, a number of barriers continue to disincentivize growth hormone use, including daily subcutaneous injections, high cost, and cultural factors.

Uncontrolled hypertension is an independent predictor for progression of CKD. Therefore hypertension should be treated with goals at or below the 90th percentile for age, sex, and height.

Uremic complications, including platelet dysfunction, bleeding, pericarditis, and encephalopathy, occur late in CKD if at all and are most commonly seen in patients with ESRD who are undialyzed or insufficiently dialyzed. Management of these complications is by aggressive dialysis. A few patients will develop nausea, fatigue, and subtle encephalopathy (usually noted as poor school performance) at lower levels of blood urea nitrogen than usually seen at ESRD. These patients may benefit from earlier institution of renal replacement therapy.

KEY POINTS: CHRONIC KIDNEY DISEASE

- The KDOQI classification system of levels of CKD is now in wide use for children, although it technically does not apply to those less than 2 years of age.
- Management of CKD includes treatment of electrolyte and acid-base imbalances, calcium and phosphorus disorders, anemia, hypertension, and growth and nutritional deficiencies.
- The multifactorial nature of CKD demands the efforts of a skilled team to manage the medical, educational, and psychosocial needs of a child and family in order to maximize the health, developmental, and social outcomes for all.

RENAL REPLACEMENT THERAPY

When renal insufficiency is so severe, either acutely or chronically, that accumulating electrolytes, waste products, or fluid are life threatening, renal replacement therapy is indicated. The incidence of ESRD in children has decreased slightly since 2008, with 1161 children beginning care for ESRD in 2012, and the prevalence has plateaued at approximately 7500 ([United States Renal Data System, 2014c](#)). The same treatment options available for adults are available for all but the smallest of premature infants, and include HD, PD, CRRT, and renal transplantation. This section reviews the indications, limitations, and necessary processes for each modality.

Dialysis

HD, PD, and CRRT are all potential therapies for severe AKI. Indications for initiation of any dialysis therapy include failure of medical management of fluid overload (including hypertension and pulmonary edema), uremia, hyperkalemia, acidosis, or other electrolyte disarray. Softer indications include the need for fluid/electrolyte removal to allow for improved nutrition or a clinical course trajectory that anticipates failure of medical management. The ideal timing of initiation of dialysis remains an area of controversy because data do not support improved renal outcomes with earlier initiation of dialysis. However, delayed initiation clearly complicates the processes for access placement and results in a more critically ill patient.

Continuous Renal Replacement Therapy

In many institutions, CRRT has become the preferred modality for the child with severe AKI, especially in the setting of fluid overload and poor cardiovascular status ([Sutherland and Alexander, 2012](#)). Advances in CRRT technology now allow for tightly controlled, gradual, constant removal of fluid and electrolytes and easy titration of extracellular fluid components even in the setting of hemodynamic instability. This may be accomplished in small children, although the smallest infants remain technically challenging patients. The advantages of CRRT include gradual yet continuous fluid and solute exchange with minimal cardiovascular instability compared to standard HD, in which the rapid high-volume extracorporeal blood flow, rapid fluid removal, and rapid electrolyte shifting are often not tolerated in an unstable patient. While PD also provides gradual removal of fluid and electrolytes, there is limited ability to control ultrafiltration and the repeated changes in intra-abdominal pressure often cause cardiorespiratory complications. Also, in acute settings wherein body wall edema is common and newly placed abdominal catheters are prone to leak, the ability to maximize dialysis and fluid removal is limited. These problems are obviated when using CRRT.

The most common CRRT method used today is continuous venovenous hemofiltration using a large-bore double-lumen venous dialysis catheter. Dialysis is accomplished using filtration alone across a semipermeable membrane, by high-clearance filtration using in-line high-volume replacement fluids, or with counter-current dialysis. Efficiency is limited by the size of the patient, size of the access, and blood flow rates tolerated by the patient. Anticoagulation is usually required and is most commonly citrate-based regional anticoagulation in which citrate is infused into the system at the exit point from the catheter, calcium is chelated, and the coagulation cascade is suppressed. Calcium is then reinfused at the entry point to the patient to maintain normal patient coagulation and calcium levels. The primary limitation of CRRT use is system clotting that occurs even with adequate anticoagulation. Smaller catheters, lower blood flow rates, and cardiac instability all increase the likelihood of circuit failure. Circuit failure usually results in significant blood loss and time off dialysis, and commonly requires access replacement (because catheter thrombosis is also frequent). Given the frequency of AKI in patients requiring extracorporeal membrane oxygenation (ECMO), the combined use of ECMO and

CRRT is also becoming more frequent. CRRT may be connected directly into ECMO circuits, and the usual heparin anticoagulation is more than sufficient to provide coverage for the additional tubing and membranes. Outcomes for pediatric patients requiring CRRT are dependent on multiple variables, including underlying disease and its severity, comorbid conditions, and degree of fluid overload. Patients with pulmonary, cardiac, or liver disease or with solid-organ/stem cell transplants have poorer outcomes (mortality rates of 49% to 69%), whereas those with renal disease, inborn errors of metabolism, and tumor lysis fare better (mortality rates of 16% to 27%) ([Sutherland et al, 2014](#)).

Peritoneal Dialysis

Acute PD may be successfully performed in any child with an intact peritoneal cavity. Given its relatively gentle nature and the lack of need of large-bore vascular catheters, PD has long been the mainstay of acute dialysis in pediatrics, especially for smaller patients. PD works by utilizing the semipermeable nature of the peritoneal membrane to accomplish exchange of water and solute. Intracapillary perfusion pressure within the membrane is quite low, but in the absence of abdominal compartment syndrome it will be higher than intra-abdominal pressure, and exchange occurs freely. However, there is no ability to titrate ultrafiltration volume and solute exchange as can be done with pumps in HD and CRRT. PD depends on osmotic pressure (using varying degrees of dextrose) to control ultrafiltration. Chronic treatments are usually nightly for 8 to 12 hours. Standard dialysate solutions are designed to remove sodium, potassium, urea, and phosphorus and deliver calcium and base equivalents (acetate or lactate) that are subsequently converted to bicarbonate. Custom-made dialysate solutions may be designed and made by hospital pharmacies for short-term use in unusual situations.

The only absolute contraindication to PD is an inadequate peritoneal cavity that may be compromised by congenital anomaly (uncorrected gastroschisis, omphalocele, or diaphragmatic hernia) or chronic sclerosis and loss of surface area from repeated surgery or infection. Acute infection and recent abdominal surgeries are relative contraindications given the unlikely nature of resolving infection with an indwelling catheter and the potential for leakage through recent incisions. However, in situations in which CRRT is likely to be ineffective or harmful (e.g., tiny infants), PD may still provide a short-term bridge even with significant risks and complications. In a recent study from Canada ([Bosch et al, 2014](#)), of 90 children receiving renal replacement therapy in a quaternary care pediatric intensive care unit, 46% received PD and 54% received CRRT, with younger and smaller children more frequently being placed on PD and larger children prescribed CRRT. The outcomes of the two groups in terms of length of stay, complications, and survival to discharge were not different. The most effective peritoneal catheter placement is surgical, with generation of a subcutaneous tunnel that decreases the risk of infection, dislodgement, and leak. Short-term use of an "acute" catheter placed with local anesthesia and the Seldinger technique is now rare because effective bedside anesthesia is now routine in the units that would offer these technologies.

For chronic dialysis, the most important decision point is actually the choice of modality ([Schaefer and Warady, 2011](#); [Warady et al, 2014](#)). The choice of HD versus PD is a complex one and includes many social factors as well as technical/medical issues. The advantage of PD is that it is designed to be provided at home. Nightly PD allows for more normal work and school schedules, and activities of daily living unencumbered by dialysis procedures. However, this requires very significant family support and investments in personal responsibility, time, energy, space, and determination, factors not always available in families with the stress of chronic illness. The complication rates of PD in families that are not able to manage these expectations are high, and ultimately increase the medical and psychosocial burden on the family. The pediatric nephrology team should assess these issues early in the evaluation of a child with advancing CKD. Advanced education

levels are not needed in the family in order to successfully manage PD, and in fact many older children and adolescents participate actively in much of their care, but the willingness to learn and dedication to standards of care are absolute requirements. The medical advantages of PD include daily dialysis that can be tailored more exactly to patient metabolic needs, less need for fluid and nutritional restrictions, preservation of vasculature, lack of blood loss, preservation of residual renal function, and improved growth compared to HD. From the perspective of a pediatric urologist, it is important to recognize that PD can be successfully accomplished in children with vesicostomies, ureterostomies, or other gastrointestinal and/or genitourinary diversions or accesses. Given the limitations in abdominal wall surface area in small children, and the need for dry, infection-free PD catheter exit sites, careful collaborative planning for surgical complications, repairs, revisions, and takedown is imperative.

While improvements continue with changes in technique and equipment, infection remains the most common complication of PD and occurs more commonly in younger children (0.85 infections per year in ages birth to 2 years) compared to older children (0.6 infections per year) (Zaritsky and Warady, 2011). Infection can affect the exit site, the catheter tunnel, and/or the peritoneal cavity. Peritonitis manifests most commonly with abdominal pain and cloudy dialysate fluid, with a diagnosis made by documenting more than 100 white blood cells/mL of fluid and greater than 50% neutrophils. The majority of peritonitis in PD is bacterial, with fungal infections accounting for less than 5% (Bosch et al, 2014). In the United States, bacterial infections are equally split between gram-positive and gram-negative organisms, although this distribution is not seen worldwide. Peritonitis is best treated with intraperitoneal antibiotics and may be successfully managed at home. The choice of antibiotics must be made with culture and sensitivity results, and intraperitoneal heparin is often used to decrease the likelihood of inflammation-induced fibrin clots and catheter dysfunction. The cure rates of infections depend on the infectious agent, with *Staphylococcus* and some gram-negative bacteria and fungi having high failure rates requiring catheter replacement. The long-term importance of PD-associated peritonitis is the association with peritoneal scarring and membrane failure leading to the loss of dialytic capacity. Membrane failure eventually occurs even in the absence of infection, so movement toward transplantation should be considered for all.

Hemodialysis

HD uses extracorporeal perfusion to accomplish clearance of water and solutes across an artificial semipermeable membrane and therefore requires large-bore vascular access. HD may be used for management of acute or chronic renal failure, and is especially effective for rapid dilute and fluid removal during shorter treatment times. HD remains a common chronic dialysis modality and is used in a bit more than half of all new ESRD starts in patients less than 19 years of age (United States Renal Data System, 2014b). However, it is much more frequently utilized in older adolescents (in whom vascular access is less problematic) and in urban areas where patients have easy access to pediatric dialysis centers. It is important to note that many states prohibit community-based dialysis units from providing treatments to patients less than age 16, which may make HD practically impossible for patients without nearby children's facilities; in those environments, PD is obviously encouraged. Advantages of HD usually focus on the minimal technical assistance required of the patient and family and the decreased treatment time. Home/nocturnal HD programs for children exist in only a few centers and are very time and labor intensive for all parties involved. Vascular access is encouraged to be via arteriovenous fistula (most commonly by an arterial-venous anastomosis in the wrist or antecubital fossa) or implantation of an artificial arteriovenous graft in the same location. However, in children less than 20 kg (and in some larger ones) these fistulae are technically difficult to create and maintain, and many children continue HD through double-lumen central catheters despite their clotting and

infection risks and known long-term damage to central vascular integrity. Complications of HD accesses include infection, catheter kinking, stenosis of fistulae inflow/outflow with potential aneurysm and thrombosis, and development of unsightly or painful venous collaterals. Thrombosis and stenosis are especially problematic in the smaller patients in whom catheter/vessel ratios are higher and blood flows are lower. Other challenges with HD include cramping, nausea, hypotension during treatments resulting from the need to remove 2 to 3 days of accumulated fluid and solutes over 3 to 4 hours, higher requirements for erythropoiesis-stimulating agents because of chronic blood loss in the circuit, and higher rates of metabolic bone disease. These problems aside, HD is especially efficient in older children with AKI in the absence of cardiovascular instability, and line placement does not require the surgical expertise needed for peritoneal catheter placement. In acute settings, HD treatments may be performed daily (or more often), and HD remains the mainstay of management of intoxications.

Renal Transplantation

The desired "end point" of all ESRD care for children is renal transplantation. Recent statistics note a significant survival benefit to transplantation over dialysis in all young age groups (United States Renal Data System, 2014c), and quality of life with a functioning graft is undoubtedly greater compared to life with dialysis. Preemptive transplantation prior to the initiation of dialysis is a goal for all patients with well-managed CKD, inactive primary diseases, and families with histories of excellent compliance. These "early" procedures occur with around 25% of pediatric transplants, the vast majority from living donors (Collins et al, 2013). Given similar graft survival rates, there is increasing use of unrelated living donors. Deceased donor graft availability remains challenging, although current regulations award elements of priority to those patients less than 18 years old and prioritize younger and healthier donors to pediatric recipients (United States Renal Data System, 2014b). These changes, as well as ongoing improvement in surgical and long-term immunosuppressive therapy management, enable recent (2003-2010) pediatric 1-year and 5-year living donor graft survival rates of 96.5% and 84.3% and deceased donor graft survival rates of 95.1% and 78.0%, respectively. Five-year graft survival for patients with congenital/structural lesions (comprising higher numbers of younger patients) is now 85% for living donor grafts and 70% for deceased donor grafts (North American Pediatric Renal Trials and Collaborative Studies [NAPRTCS] Data Coordinating Center, 2010). Contraindications to renal transplantation are few and include active malignancy, multisystem organ failure, and concerns of severe nonadherence. Previous barriers such as HIV infection, ABO blood group incompatibility, and T-cell crossmatch positivity are no longer absolute contraindications but do require special preparative and postoperative management procedures that are not routinely available in all centers. Similarly, transplantation in the presence of diseases with high rates of recurrence post-transplant (FSGS, inherited forms of HUS, or primary oxalosis) should occur within programs that are capable of accomplishing the unique strategies most likely to result in long-term graft success. Renal transplantation in the infant remains rare because of higher technical failure rates. The vast majority of programs aspire to aggressive nutrition and growth in babies with the goal of transplantation at around 10 kg.

Postsurgical immunosuppression now most commonly includes antibody induction with either anti-T cell preparations or interleukin-2 receptor blockade followed by tacrolimus, mycophenolate mofetil, and prednisone (NAPRTCS Data Coordinating Center, 2010). Steroid-sparing and steroid-free protocols are now more common and have not significantly changed the acute rejection rates. The success of these immunosuppression regimens can be noted in the now 10% rate of rejection within the first year for all donor types, having been approximately 50% in 1997 (United States Renal Data System, 2014b). The expected side effects of increased infection and malignancy rates are noted, with approximately 10% of all deaths after pediatric transplantation attributable

to malignancy (Mynarek et al, 2014), as are consistent increases in Epstein-Barr virus and BK virus complications.

Involvement of pediatric urologists in the planning, evaluation, and management of renal transplantation is key, but the extent of involvement in each area varies significantly based on center design and individual patient needs. Patients with congenital urinary tract anomalies are usually well known to their pediatric urologists, who will seamlessly transition into the planning and management needed to ensure adequate lower urinary tract function after transplantation. Other patients (primarily those with cystic or acquired disorders) may never have had urologic complaints and come to urology for the first time during evaluation for transplantation. Therefore, transplantation evaluation and management may include a wide range of potential studies from basic determinations of urinary tract health and urodynamics all the way to complex surgical correction of preexisting abnormalities and creation of urinary reservoirs or drainage systems. The role of the pediatric urologist in the transplant event itself is most commonly determined by patient needs and program tradition, but it is also important for the pediatric urologist to remain available and involved even long after the transplant procedure in order to maintain careful and expert observation and management of the urinary tract as the patient continues to grow and mature. Urinary tract infections post-transplant are also often recalcitrant to treatment, especially in patients with complex anatomy, and urologic expertise to maximize drainage is imperative to save functional renal tissue and prevent systemic spread of infection.

KEY POINTS: DIALYSIS AND RENAL TRANSPLANTATION

- CRRT by continuous venovenous hemofiltration is increasingly used as the primary dialysis therapy for children with severe AKI in the setting of multisystem organ failure.
- PD is the most common renal replacement therapy used for small infants, and remains a common choice throughout the pediatric age range for its opportunities to maintain school attendance and home management.
- PD can be successfully maintained in small infants with urinary diversions but requires careful collaboration between the urology and nephrology teams.
- HD is rapid and highly efficient, but is more technically feasible in larger children.
- Choice of chronic dialysis modality is best made with careful consideration of patient/family psychosocial factors, anticipated nutritional needs, expected time to consideration for transplantation, and near-term surgical needs.
- Renal transplantation offers the best long-term outcomes for children with renal disease and should be aggressively considered.
- Children with complex anatomy, rare diseases, or disorders likely to recur post-transplantation, or those with other complicating factors, should have transplantation planning and management organized in experienced centers.

SUMMARY

Effective collaboration between pediatric nephrologists and pediatric urologists is of utmost value to children with renal disease. Many areas of practice overlap, and while there may be differences in opinion regarding best approaches, there is rich advancement in careful appreciation of the expertise of both specialties. Both specialties have increasingly expert teams of health care providers who add support and guidance to families managing these complex issues. Our success in caring for these disorders has clearly improved and, working together, we have even more to offer future generations of children with kidney and urinary tract disease.

124 Perinatal Urology

Richard S. Lee, MD, and Joseph G. Borer, MD

Fetal Imaging

Fetal Diagnosis

Specific Diagnoses

Antenatal Management of Fetal Uropathies

Postnatal Management of Antenatally Detected Urologic Renal Abnormalities

Neonatal Urologic Emergencies

Summary

FETAL IMAGING

The increased use of maternal-fetal ultrasound has led to the development of the field of perinatal urology. **Antenatal hydronephrosis (ANH)** is identified in 1% to 3% of all pregnancies and is one of the most common birth defects detected (Livera et al, 1989; Blyth et al, 1993; Gunn et al, 1995; Sairam et al, 2001; Shamshirsaz et al, 2012). In addition to hydronephrosis, renal cystic disease, renal agenesis, stones, and tumors have also been diagnosed prenatally. For the urologist, these prenatal findings have created numerous challenging clinical and scientific dilemmas.

Ultrasonography continues to be the mainstay of fetal imaging. With experience, this modality provides intricate detail and diagnostic capability that is similar to that of ultrasonography in the neonate. Ultrasound evaluation facilitates screening of large numbers of fetuses with no radiation exposure and is nearly universally available. The potential advantages of three-dimensional (3D) ultrasonography in imaging of urologic diagnoses are unclear.

Fetal magnetic resonance imaging (MRI) is a valuable adjunct when further delineation of anatomic detail is believed to be necessary to optimize diagnosis and/or management strategy (Estroff, 2009; Storm et al, 2011; Chauvin et al, 2012). As with ultrasonography, there is no radiation exposure. Use of complementary computed tomography is controversial because the additive information may not outweigh the added risk of fetal and maternal radiation exposure.

The discussion here centers on the diagnosis of prenatal urologic abnormalities and the postnatal implications, the rationale behind prenatal intervention, and clinical experience in managing children with prenatal and neonatal urologic abnormalities. Further detailed discussion regarding evaluation and management of many of these entities when they occur beyond the perinatal period is presented in other chapters in this textbook.

FETAL DIAGNOSIS

A large prospective study of 11,986 Swedish women conducted between 1978 and 1983 identified renal anomalies in 0.28% of fetuses; over two thirds of the anomalies were hydronephrosis (0.18%) (Helin and Persson, 1986). Similarly, a British prospective screening study of 6292 pregnant women at 28 weeks' gestation demonstrated hydronephrosis in 1.40% of patients, with postnatal confirmation in 0.65% (Livera et al, 1989). These authors defined ANH as an **anteroposterior diameter (APD)** of the renal pelvis greater than 5 mm but noted the lack of consensus on the definition of ANH (Scott and Renwick, 1993; Scott et al, 1995; Scott and Renwick, 1999). With the rapid improvement of ultrasound technology, the incidence of detection of renal anomalies may be

changing. In a more recent prospective cohort study (1999 to 2003), a 0.76% incidence of urinary tract abnormalities was detected that was increased as compared with an earlier cohort from the same institution (0.3%, 1989 to 1993) (Mallik and Watson, 2008). However, many variations in the definition and management of ANH exist in the literature and clinical practice, including method and frequency of in utero testing, radiographic documentation, classification, and postnatal management (Benacerraf et al, 1990; Corteville et al, 1992; Fernbach et al, 1993; Adra et al, 1995; Thompson and Thilaganathan, 1998; Chudleigh et al, 2001; Lee et al, 2006). This variability may significantly alter the incidence reported within the literature.

Regardless, when an abnormality of the urinary tract is determined by antenatal ultrasonography, several questions should be raised by the ultrasonographer and consulting urologist. Combinations of specific findings direct the differential diagnosis and permit a more accurate prognosis and tailoring of postnatal evaluation. The principal findings and their implications are listed in Table 124-1.

Diagnostic Findings

Kidney

There are critical elements to an antenatal ultrasound examination that may help identify urologic pathology. A constellation of aberrations may indicate pathology, particularly when placed in context with other clinical findings. Specific details of the examination need to be reported to assist antenatal counseling. **The ultrasound evaluation of the kidney should comment on number, location, size, duplication, renal parenchyma (echogenicity), pelvic dilation, calyceal dilation, urothelial thickening, and cystic disease.**

Kidneys should be the appropriate size for gestational age and relatively symmetrical (Chitty and Altman, 2003). Large differences in size may indicate contralateral compensatory growth. Absence of the kidney in the normal location may represent ectopia or agenesis or dysplasia. **The normal kidney should be elliptical and have distinctive internal echolucency, representative of normal medullary pyramids (Fig. 124-1).** The appearance of the medullary pyramids should not be confused with renal calyceal dilation. The echogenicity of the kidney should be slightly less than that of the corresponding spleen or liver. Abnormalities of echogenicity with or without hydronephrosis may indicate renal disease. Isolated increased echogenicity has been associated with renal parenchymal disorders, but it has also been shown to be of no clinical significance (Estroff et al, 1991; Carr et al, 1995; Mashiach et al, 2005). When occurring with hydronephrosis it may indicate renal dysplasia, particularly if there is accompanying decreased amniotic fluid (Kaefer et al, 1997b).

TABLE 124-1 Elements of Prenatal Urologic Ultrasonographic Diagnosis

PARAMETER	COMMENT	POSSIBLE CAUSES
Hydronephrosis	Variable severity; may include pelviectasis and/or caliectasis	Obstruction, reflux
Caliectasis	Intrarenal dilation; more indicative of significant pathologic process	Obstruction, reflux
Pelvic anteroposterior diameter	Measured in the coronal plane, variable; in extremes may predict clinical outcome; caution should be exercised in overreliance on these measurements	Increased in obstruction, reflux
Renal parenchyma	Echogenicity should be less than that of liver or spleen; lucent medullary pyramids should be seen	Increased echogenicity in dysplasia, obstruction, ARPKD
Urothelial thickening	Increased thickness of pelvic lining	Variable dilation as with reflux or occasionally obstruction
Duplication	Separation of renal pelvic sinus echoes when no hydronephrosis seen	Possible associated reflux or obstruction; look for dilated ureter and ureterocele
Cystic structures, renal	Simple cysts rare	MCDK, ADPKD
Cystic structures, intravesical	May be very large and fill bladder; thin walled	Ureterocele
Urinoma	Fluid collection around kidney; perinephric or subcapsular	Obstruction
Bladder filling	Fill and void cycles may be demonstrated over time	Urine production
Bladder wall thickness	Must be interpreted in context of bladder filling	Obstruction, neurogenic dysfunction
Keyhole sign	Dilated posterior urethral; difficult to image	Posterior urethral valves
Oligohydramnios	Markedly reduced amniotic fluid; usually considered as no pocket of fluid >2 cm	Poor urine output because of obstruction and/or renal failure

ADPKD, autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; MCDK, multicystic dysplastic kidney.

Figure 124-1. Ultrasound appearance of normal fetal kidney with echolucent medullary pyramids distinguishable from the more echogenic cortical parenchyma. The cortical parenchyma should be of lower echogenicity than adjacent liver or spleen.

Figure 124-2. Multicystic dysplastic kidney with large, multiple, variable-sized cysts without a central large cystic area. As here, most cases show virtually no parenchyma.

Renal cystic disease can be seen in utero. Autosomal recessive polycystic kidney disease (ARPKD) may manifest with large, bright or echogenic kidneys because the numerous small renal cysts cannot be resolved by ultrasonography. In contrast, a multicystic dysplastic kidney (MCDK) typically manifests as a large noncommunicating macrocyst (Fig. 124-2). A single cyst may represent a dilated renal calyx or diverticulum, an atypical MCDK, severe hydronephrosis, or a nontribal structure.

Ureter, Bladder, and Urinoma

In addition to kidney-specific findings, ureteral dilation, bladder filling and emptying, bladder wall thickness, intravesical cystic structures, dilation of the posterior urethra (keyhole sign), urinoma, amount of amniotic fluid, intra-abdominal or pelvic mass, and external genitalia should be noted. **Hydroureter is best seen in cross section of a full bladder but is often difficult to detect**

(Fig. 124-3). Duplication and ureteral ectopia may also make this a difficult diagnosis.

Although the bladder is sometimes difficult to image well, visualization of the bladder can be very informative because a full bladder implies renal function. Inability to identify the bladder on repeat studies should raise the question of bladder exstrophy. Increased bladder wall thickness may indicate outlet obstruction, and dilation of the posterior urethra (keyhole sign) is strongly suggestive of posterior urethral valves (Fig. 124-4). In duplex

Figure 124-3. Fetal ultrasonography showing a dilated, tortuous ureter (arrow). These may be associated with reflux, valves, ectopic ureters, ureterocele, and ureterovesical junction obstruction. In this case the ureter is associated with a dilated upper pole indicating an ectopic ureter or ureterocele.

Figure 124-4. Fetal ultrasonography at 22 weeks' gestation of a male with posterior urethral valves. The bladder is thick walled and has a dilated posterior urethra (keyhole sign). There was also bilateral hydronephrosis, echogenic renal parenchyma, and a perinephric urinoma.

systems, ureterocele may manifest as an intravesical cystic structure and a dilated upper pole.

Perineal urinoma may indicate an obstructive condition (Yerkes et al, 2001) (Fig. 124-5). Typically it will have the appearance of an anechoic structure around the kidney or be in a subcapsular location. When identified, a urinoma or urinary ascites is often associated with severe bladder obstruction or posterior urethral valves, in which the urinoma may indicate a pop-off mechanism. A urinoma also may be associated with a unilateral hydronephrotic or obstructed kidney (Mandell et al, 1994). The pop-off mechanism may be renal protective, particularly in cases of lower urinary tract obstruction (Adzick et al, 1985; Adorisio et al, 2011).

Amniotic Fluid

Critical to the evaluation of the urinary tract is the assessment of the amniotic fluid level and changes during pregnancy. After 16 weeks, amniotic fluid production shifts from placental transudate to fetal urine; and by 20 to 22 weeks the vast majority of amniotic fluid is fetal urine (Takeuchi et al, 1994). Consequently, reduced amniotic fluid or oligohydramnios identified after 18 to 20 weeks' gestation may be a result of urinary tract obstruction or poor renal development (Stiller et al, 1988).

External Genitalia

Proper identification of the external genitalia also can be very valuable in cases of gender-specific diagnoses, such as posterior urethral valves. In cases of virilization (e.g., congenital adrenal hyperplasia [CAH]), a clitoris may appear as a small phallus; therefore the presence of scrotal testes is critical for male gender assignment (Benacerraf et al, 1989; Bromley et al, 1994; Mandell et al, 1995). Megalourethra, or a dilated, elongated penile urethra, may be an isolated anomaly or associated with prune-belly syndrome (Dillon et al, 1994) (Fig. 124-6). Bilateral renal obstruction and bladder outlet obstruction in a female fetus would suggest a cloacal anomaly (Cilento et al, 1994; Ohno et al, 2000; Taipale et al, 2004) (Fig. 124-7).

Hydronephrosis

Hydronephrosis, or dilation of the renal pelvis, is the most common urologic abnormality found on ultrasound evaluation.

Figure 124-5. Appearance of a fetal perinephric urinoma associated with posterior urethral valves.

Figure 124-6. Fetal ultrasound appearance of a male with a dilated and patulous urethra typical of a megalourethra. This may be seen in prune-belly syndrome as well as in isolation. This child also had marked vesicoureteral reflux.

Figure 124-7. Fetal magnetic resonance image illustrating severe bladder dilation (*black arrow*) and a separate dilated pelvic structure behind the bladder (*white arrow*) in a female fetus at 22 weeks' gestation. The kidneys were bilaterally and symmetrically dilated with ureteral distention. This pattern can be seen with oligohydramnios and represents a urogenital sinus malformation with bladder outlet obstruction caused by vaginal distention from urine flowing into the urogenital sinus.

Figure 124-8. Severe fetal hydronephrosis with diffuse calyceal dilation arrayed around the markedly dilated renal pelvis. The renal parenchyma is stretched over the dilated collecting system, but this does not mean loss of functional potential. Corticomedullary differentiation is difficult to see in this configuration.

Numerous grading systems have been developed; however, there is no consensus on the best and most consistent method of reporting ANH (Fig. 124-8) (Fernbach et al, 1993). Measurement of the APD has been used widely, but there have been no formal studies to determine the interobserver and intraobserver reproducibility of ANH measurement. One of the disadvantages of use of the APD can be the failure to describe pelvic configuration, calyceal dilation, and the laterality of findings, which should be included. The APD can be affected by gestational age, hydration status of the mother, bladder hypertonicity, and degree of bladder distention. Because the dimensions of the renal pelvis may normally increase with gestational age, most investigators have adjusted threshold APD values for early and later gestational age. Unfortunately, a simple threshold APD value that separates normal from abnormal does not exist, because even severe cases of ANH have the potential to resolve without incident, whereas mild degrees of ANH have the potential to progress (Pates and Dashe, 2006).

Varying the minimal APD threshold can significantly alter the specificity and sensitivity of APD as a measure of ANH and postnatal pathology. To date there is no consensus on the optimal APD threshold for determining the need for postnatal follow-up. An APD cutoff of 15 mm for determining obstruction yielded a postnatal sensitivity of 73% and specificity of 82% (Coplen et al, 2006). A late gestational age APD cutoff of 10 mm would detect approximately 23% of abnormal kidneys, whereas a cutoff of 7 mm detected 68% (Ismaili et al, 2003). One large systematic review estimated that only 11.9% of total pathology included late gestational age APD of less than 9 mm, whereas 39% of total pathology was noted at APD levels below 15 mm (Lee et al, 2006). Nearly identical results have been demonstrated by other investigators (Wollenberg et al, 2005). What appears certain is that lower cutoffs will be more sensitive in detecting postnatal pathology but will incur a higher false-positive rate.

Categorizing Antenatal Hydronephrosis by Anteroposterior Diameter. There is near-total agreement that APD greater than 15 mm represents severe or significant hydronephrosis, and some would also agree that a lower threshold of 4 to 5 mm is an appropriate value for considering APD to be abnormal (Feldman et al, 2001; Ahmad and Green, 2005; Wollenberg et al, 2005; Lee et al, 2006; Coelho et al, 2007, 2008). Taking these limitations into consideration, we define ANH in the second and third trimesters using APD thresholds for which the best available evidence provides

prognostic information; along with these definitions the estimated distribution of the ANH based on the previously defined definition of APD is outlined in Table 124-2.

Alternative Measurements. The use of alternative grading systems, 3D volume measurements of the renal pelvis, or a hydronephrosis index to correct for bladder distention may provide a more precise evaluation of ANH (Duin et al, 2008; Nam et al, 2012). Some investigators have considered use of the Society for Fetal Urology (SFU) ultrasound grading system to classify ANH (Kim et al, 2013). MRI may also prove useful in prenatal evaluation with the advantages of high anatomic detail without ionizing radiation exposure. However, high cost and limited data currently confound the optimal use of this modality in the context of ANH (Savelli et al, 2007).

Diagnostic Accuracy

As both ultrasound and MRI technology improve, more accurate radiographic information is obtainable (Laifer-Narin et al, 2007). However, determining accurate postnatal diagnosis and prognosis remains challenging. Regardless of the diagnosis, early intervention is uncommon except in the potential case of severe obstruction or posterior urethral valves. In the vast majority of other cases, early

detection of ANH may be an impetus for future postnatal evaluation.

The ability to determine definitive postnatal pathology based on antenatal findings is difficult. As an example, in a systematic review of the ANH literature, Lee and colleagues attempted to determine the risk of a pathologic diagnosis for patients with varying severity of ANH (Lee et al, 2006). The review included 1308 patients who were identified with ANH and sufficient postnatal radiographic follow-up. The degree of ANH was defined by APD identified in a particular trimester. Approximately 36% of the patients had a postnatal pathologic diagnosis, and the overall risk for any pathologic process increased with increasing degree of ANH (Table 124-3). However, the risk of vesicoureteral reflux (VUR) remained consistent regardless of the degree of ANH, thereby implying that ANH is not an appropriate indicator for VUR.

Although earlier literature suggests that obstruction location can be determined prenatally in 88% of cases, many other researchers have reported a high false-positive rate (9% to 22%) (Hobbins et al, 1984; Scott and Renwick, 1993). The majority of false-positive findings in these studies involved nonobstructive causes of hydronephrosis, such as high-grade reflux, large nonobstructed extrarenal pelves, or transient hydronephrosis.

Early and accurate diagnosis of posterior urethral valves is critical; however, it can be difficult. The hallmark signs of an in utero diagnosis of posterior urethral valves have been described (e.g., oligohydramnios, dilated posterior urethra, thickened bladder, and hydroureteronephrosis). Other findings such as increased renal echogenicity and decreased amniotic fluid have also been suggested to be indicative of obstructive conditions (Kaefer et al, 1997b). Regardless, there are very few studies that have prospectively examined the clinical urologic implications of these findings alone or in combination (Lee et al, 2006). In one series of 22 fetuses, the false-positive rate was as high as 58% (Abbott et al, 1998), and in a population-based series the sensitivity in detecting valves was as low as 23% (Scott and Renwick, 1993).

Regardless of the degree or severity of the finding, after any antenatal detection of a urinary tract anomaly a thorough fetal survey must be conducted. Amniocentesis and karyotype should be considered if intervention or a major anomaly is

TABLE 124-2 Definition of Antenatal Hydronephrosis by Anterior Posterior Diameter and Estimated Severity Percentage Range

DEGREE	ANTEROPOSTERIOR DIAMETER		SEVERITY
	SECOND TRIMESTER	THIRD TRIMESTER	
Mild	4 to <7 mm	4 to <9 mm	56.7%-88.0%
Moderate	7 to ≤10 mm	9 to ≤15 mm	10.2%-29.8%
Severe	>10 mm	>15 mm	1.5%-13.4%

suspected, because the incidence of concurrent chromosomal anomalies is relatively high in fetuses with concomitant urologic anomalies (Callan et al, 1990; Nicolaides et al, 1992; Snijders et al, 1995).

KEY POINTS: PRENATAL DIAGNOSTIC FINDINGS

- Ultrasonography is the mainstay of prenatal imaging. Selective use of fetal MRI may further delineate anatomic details and help with diagnosis and management.
- The normal kidney should be elliptical and have distinctive internal echolucency, representative of normal medullary pyramids.
- The appearance of the medullary pyramids should not be confused with renal calyceal dilation.
- Inability to identify the bladder on repeat studies should raise the question of bladder exstrophy.
- Dilation of the posterior urethra (keyhole sign) is strongly suggestive of posterior urethral valves.
- Reduced amniotic fluid or oligohydramnios identified after 18 to 20 weeks' gestation may be a result of urinary tract obstruction or poor renal development.
- Hydronephrosis, or dilation of the renal pelvis, is the most common urologic abnormality found on ultrasonography and is typically measured by the APD of the renal pelvis.
- The APD fails to describe pelvic configuration, calyceal dilation, and the laterality of findings.
- A threshold APD value that separates normal from abnormal does not exist.
- The risk of VUR per degree of ANH is similar, implying that ANH is not an appropriate indicator of VUR.
- Antenatal detection of any urinary tract anomaly should prompt a thorough fetal survey.

SPECIFIC DIAGNOSES

Ureteropelvic Junction Obstruction

The basic features of ureteropelvic junction (UPJ) obstruction in the fetus include dilation of the renal pelvis and collecting system with no evidence of ureteral dilation. Lee and associates (2006) demonstrated that increasing severity of ANH increased the likelihood of identifying postnatal UPJ obstruction. However, the threshold for recommending postnatal follow-up is largely arbitrary, and currently there are no long-term prospective studies to determine the degree of postnatal evaluation, particularly for mild and moderate cases of ANH. Nevertheless, in the case of significant unilateral hydronephrosis there is little rationale for in utero intervention or early delivery. In a few cases with massive dilation, therapeutic aspiration has been recommended for prevention of dystocia. In the case of bilateral UPJ obstruction the efficacy of in utero intervention is difficult to assess. Severe forms of UPJ obstruction may be associated with urinary ascites or perinephric urinomas, which may be a predictor of nonfunction of the kidney (Mandell et al, 1994; Adorisio et al, 2011).

Ureterovesical Junction Obstruction

Less common than UPJ obstruction, ureterovesical junction (UVJ) obstruction is characterized by ureteral dilation along with varying degrees of renal pelvic and calyceal dilation. The best way to detect ureteral dilation is at the level of the bladder, preferably in the transverse view. It is not uncommon for the distal ureter to be more dilated as compared proximally. The causes of this appearance may be primary obstruction of the UVJ, ectopic ureter inserting into the bladder neck, or high-grade VUR. Typically, the differentiation is made postnatally.

Cystic Kidneys

The distinction between severe unilateral hydronephrosis and MCDK occasionally may be unclear. The findings of multiple noncommunicating cysts, minimal or absent renal parenchyma, and the absence of a central large cyst are diagnostic of MCDK (Bearman et al, 1976; Sanders and Hartman, 1984). The appearance of noncommunicating cysts is essential to the diagnosis and should be distinguished from severe hydronephrosis (see Fig. 124-2). Real-time examination of the kidneys to help determine the communication of the calyces is essential. Doppler ultrasonography of the renal vasculature pulse pattern has also been reported to help make the distinction (Kaminopetros et al, 1991).

MCDK may be present in any ectopic location but typically is in the normal position. In addition, MCDK can be present in a duplex kidney, typically the upper pole. If detected early in the pregnancy, the MCDK will often involute over a period of time either prenatally or postnatally (Mandell et al, 1994).

Bilaterally enlarged echogenic kidneys without renal cystic disease, particularly if associated with hepatobiliary dilatation or oligohydramnios, suggest ARPKD (Smedley and Bailey, 1987; Townsend et al, 1988) (Fig. 124-9). Typically this is identified before 20 weeks' gestation, but later development has been reported (Mandell et al, 1991; Zerres et al, 2004). Genetic testing is possible in some cases, thereby allowing for early diagnosis and the option for early termination because postnatal mortality and morbidity are high (Wilson, 2004; Zerres et al, 2004).

The more challenging findings are normal-sized, diffusely echogenic kidneys that are not associated with other urologic lesions (Tsatsaris et al, 2002; Mashiach et al, 2005). A series of 19 cases (14 bilateral) included 10 patients with normal function who survived and 4 with ARPKD who died (Carr et al, 1995). In a separate multicenter retrospective study of 93 fetuses with hyperechogenic kidneys and a later diagnosis of nephropathy of varying cause, only one third of the fetuses had renal cysts irrespective of their diagnosis; 28 had ARPKD (only 3 with cysts) and 31 had autosomal dominant polycystic kidney disease (ADPKD) (9 with cysts). Typically, those with ADPKD appeared to have moderately enlarged hyperechogenic kidneys with increased corticomedullary differentiation. In addition, as opposed to renal cyst characteristics, associated malformations were the most helpful clue to identify a diagnosis (Chaumoitre et al, 2006).

Figure 124-9. Bilaterally enlarged, echogenic kidneys without grossly apparent cysts are typical of autosomal recessive polycystic kidneys. This appearance usually, but not always, becomes apparent by 22 weeks of gestation. In early-onset cases, oligohydramnios is seen.

Macrocystic disorders include the rare congenital multilocular cystic nephroma, which is characterized by segmental involvement of the kidney with variable macrocysts (Eble and Bonsib, 1998); cystic Wilms tumor, which typically has larger amounts of functioning parenchyma; and ADPKD, which may include heterogeneous cysts in size, location, and number (Reeders et al, 1986; McHugo et al, 1988; Ceccherini et al, 1989; Novelli et al, 1989).

Nonrenal cystic diseases can be confused with MCDK; however, these cystic anomalies are typically not in the renal fossa, and the conditions are unlikely to be confused in the presence of two normal kidneys. These cystic conditions include mesenteric duplication cysts, neurenteric cysts, bronchogenic cysts, extrathoracic pulmonary sequestration, and cystic neuroblastoma (Barr et al, 1990; Bagolan et al, 2000; Carpentieri et al, 2000; Granata et al, 2000; Uludag et al, 2001).

Duplication Anomalies and Ureterocele

Duplication anomalies are often recognized on the basis of upper pole hydroureteronephrosis, associated with either an obstructing ureterocele within the bladder or an ectopic ureter inserting outside the bladder (Vergani et al, 1999). Ureteroceles are identified as an intravesical, thin-walled cystic structure near the base of the bladder (Fig. 124-10). In cases of a very large ureterocele, the ureterocele may be mistaken for the bladder. Alternatively, in the setting of a ureterocele the upper pole may not always show hydronephrosis. The upper pole may appear as a cystic dysplastic unit without hydronephrosis and a concomitant ureterocele. This is often termed *ureterocele disproportion* (Share and Lebowitz, 1989). In addition, single-system ureteroceles are more likely to occur in boys and have variable degrees of hydronephrosis of the entire kidney.

Lower pole hydronephrosis may be present as a result of VUR (Fig. 124-11) or more rarely a lower pole UPJ obstruction. Occasionally, lower pole dilation is caused by obstruction of both the upper and lower pole ureter by a large ureterocele. Similarly, bilateral hydronephrosis may be secondary to an element of bladder outlet obstruction from prolapse of the ureterocele into the bladder neck (Sozubir et al, 2003).

In the absence of a ureterocele, upper pole hydroureteronephrosis suggests an obstructed ectopic ureter (Abuhamad et al, 1996). The dilated ectopic ureter can be mistaken for a ureterocele because of the impression that it creates on the back wall of the bladder. However, typically the ectopic ureter is much thicker than a ureterocele. Bilateral single-system ectopic ureters are uncommon but typically manifest with echogenic renal parenchyma, cystic disease, minimal bladder volume, and low amniotic fluid levels.

Figure 124-10. Fetal ultrasonography showing an intravesical ureterocele. The ureterocele is indicated by the arrows and partially fills the bladder. With this finding the ultrasonographer should examine the upper tracts to determine whether there is hydronephrosis in the entire affected kidney or only the upper pole, as shown in Figure 124-3.

Figure 124-11. A, Image of a fetus at 28 weeks' gestational age with left lower pole hydronephrosis, hydroureter, and a ureterocele. B, Postnatal voiding cystourethrogram demonstrating lower pole vesicourethral reflux and the ureterocele.

Vesicoureteral Reflux

VUR cannot be definitively diagnosed on prenatal ultrasonography, although intermittent or varying degrees of hydronephrosis or hydroureter are suggestive of the diagnosis. Several studies have demonstrated that a high incidence of VUR is associated with prenatally detected hydronephrosis; however, the true incidence of VUR in children with a history of ANH is difficult to determine based on the variability of postnatal diagnostic management in the literature (Lee et al, 2006). In two systemic reviews of the ANH literature a 10% to 15% incidence of VUR was identified regardless of the degree of ANH (Lee et al, 2006; van Eerde et al, 2007), indicating that the severity of ANH is not indicative of VUR and may not be the appropriate trigger for postnatal evaluation. In a neonate with prenatally detected hydronephrosis, the importance of diagnosing VUR remains controversial, because VUR diagnosed on postnatal evaluation for ANH is associated with earlier resolution of VUR (Estrada et al, 2009; Skoog et al, 2010).

Posterior Urethral Valves

Perhaps the most important diagnosis to be made prenatally is that of posterior urethral valves in the male fetus. At the very least the finding of posterior urethral valves mandates prompt postnatal intervention, and in some cases prenatal intervention may be warranted. Fetal ultrasound findings include bilateral hydronephrosis, a thick-walled bladder with dilated posterior urethra, and, in more severe cases, dysplastic renal parenchymal changes with perinephric urinomas and urinary ascites (see Fig. 124-5) (Bellinger et al, 1983; Reuter and Lebowitz, 1985; Barakat et al, 1991; Dinneen et al, 1993; Hutton et al, 1994; Gunn et al, 1995; Kaefer et al, 1997a; Abbott et al, 1998). Massive bladder dilation can be seen to occupy a good proportion of the abdomen (Fig. 124-12). With progression of the pregnancy, the bladder may become more thick walled with increasing posterior urethral dilation (see Fig. 124-4). When characteristic ultrasound findings are present, the differential diagnosis includes prune-belly syndrome (with or without urethral atresia), massive VUR, and certain

Figure 124-12. Fetal magnetic resonance image showing massive bladder distention from posterior urethral valves. The dilated posterior urethra is seen below the bladder and indicated by the arrow.

cloacal anomalies (in genetic females) (Kaefer et al, 1997a; Oliveira et al, 2000; Osborne et al, 2011).

Bladder Exstrophy

Bladder exstrophy is a congenital abnormality affecting development of the lower abdominal wall, lower urinary and reproductive tracts, and musculoskeletal system. Prenatal diagnosis can be made with reasonable certainty using ultrasonography. Common observations in the fetus with bladder exstrophy include nonvisualization of the fetal bladder, a lower abdominal wall mass immediately inferior to a low-lying umbilicus, and diminutive genitalia (Gearhart et al, 1995). Patience and expertise in the ultrasonographer are important for recognition of the consistent negative finding on fetal imaging—absence of bladder filling—that is critical in making the diagnosis of bladder exstrophy. Other findings that may be evident to the experienced observer include normal kidneys in orthotopic position, normal vertebrae and spinal cord, abnormal symphyseal diastasis, and anteriorly displaced anus (Fig. 124-13). Additional prenatal MRI may be beneficial in excluding other cloacal anomalies and confirming the diagnosis of bladder exstrophy (Goldman et al, 2013).

Prenatal diagnosis of bladder exstrophy provides an opportunity for discussion of bladder exstrophy, complex reconstruction in neonates, follow-up care and outcomes, other organ system normality, and options of termination versus continuation of the pregnancy (Cacciari et al, 1999; Bischoff et al, 2012). The increasing ability to accurately diagnosis this and other complex diagnoses may have led to an increase in termination (Cromie et al, 2001).

Increasingly, the initial management of the newborn with bladder exstrophy is, perhaps, believed not to present an emergency state, and prenatal diagnosis may be helpful for several reasons. For example, at a center of excellence, expectant parent(s) who are interested may be offered advanced obstetric care, interaction with the pediatric urologic team, introduction to the pediatric hospital's support services, familiarity with the pediatric hospital itself, and interaction with parents of a child with bladder exstrophy.

Cloacal Exstrophy

Cloacal exstrophy (omphalocele, exstrophy, imperforate anus, spinal abnormality [OEIS]) is the most severe manifestation of the exstrophy-epispadias complex spectrum, carrying all of the findings associated with bladder exstrophy and renal, spinal, and bowel involvement in the form of a lateral enterovesical fistula. Cloacal exstrophy describes a rare grouping of component malformations. The cause is unknown but likely heterogeneous. Although postnatal identification of its associated gastrointestinal, spinal, and genitourinary systems delineates the extent and natural history of OEIS complex, prenatal findings may provide additional information regarding early detection, possible causative factors, and outcome. The association of twinning and OEIS complex suggests that abnormal developmental step(s) may occur as early as blastogenesis (Keppler-Noreuil, 2001; Keppler-Noreuil et al, 2007). Based on fetal ultrasound findings, Casale and colleagues (2004) raised a possible role of blighted conjoined twinning as a cause of cloacal exstrophy variants.

The prenatal diagnosis of cloacal exstrophy should be suspected with findings of nonvisualization of the bladder in association with a low-lying umbilicus, lower abdominal wall mass—typically omphalocele—and kidney (number, location, and/or appearance) and lumbosacral spine abnormalities (Fig. 124-14). Austin and colleagues (1998) reviewed 22 patients with prenatal ultrasound studies and cloacal exstrophy; they identified relatively common “major” criteria for prenatal diagnosis of cloacal exstrophy of nonvisualization of the bladder, a large midline infra-umbilical anterior wall defect, omphalocele, and lumbosacral anomalies and less frequently observed “minor” criteria including lower extremity defects, renal anomalies, ascites, widened pubic arches, hydrocephalus, and one umbilical artery. Additional ultrasound findings suggestive of cloacal exstrophy in the fetus include

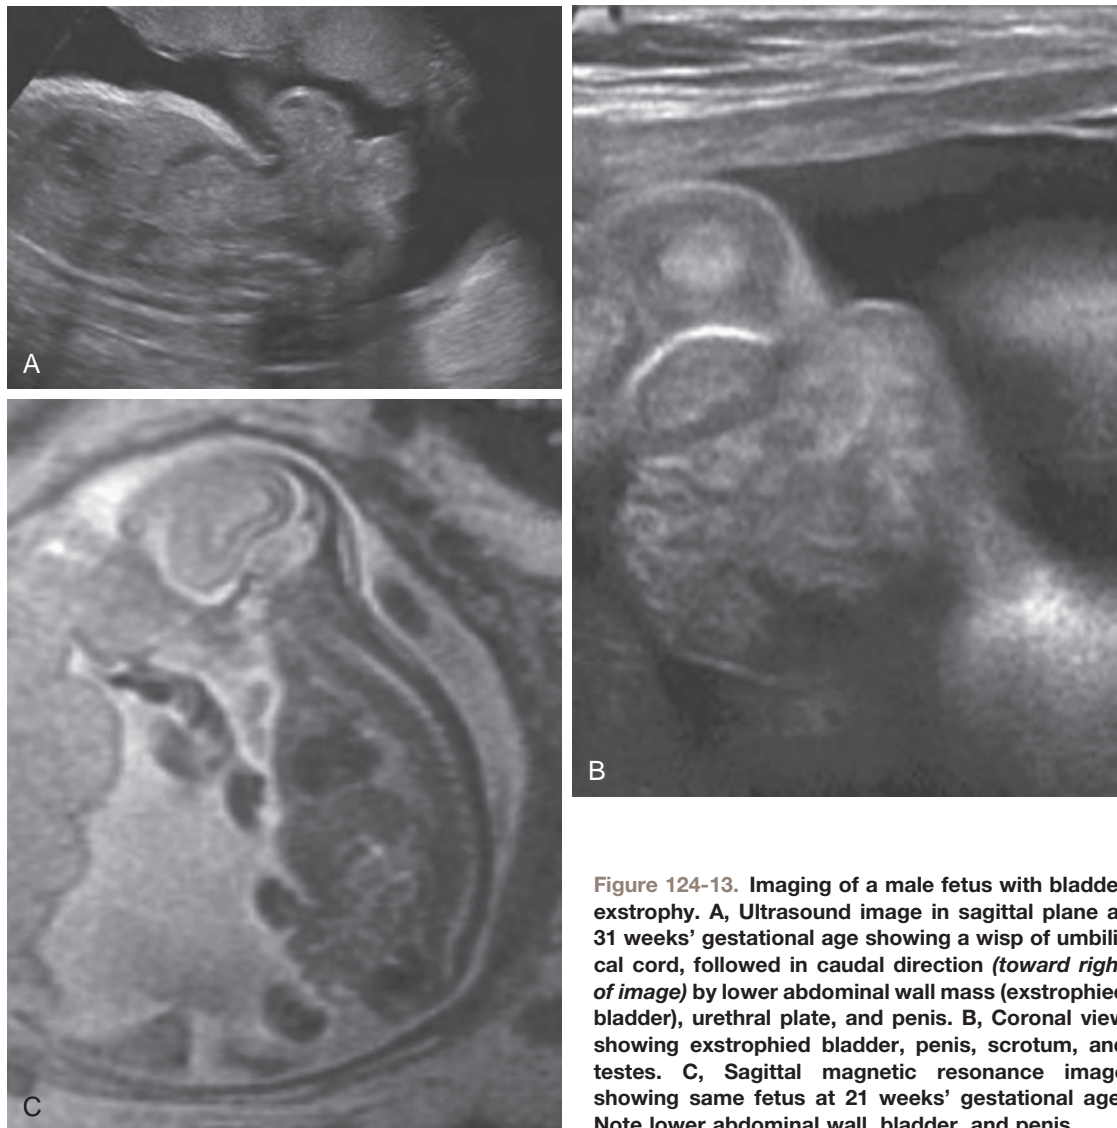

Figure 124-13. Imaging of a male fetus with bladder exstrophy. **A**, Ultrasound image in sagittal plane at 31 weeks' gestational age showing a wisp of umbilical cord, followed in caudal direction (*toward right of image*) by lower abdominal wall mass (exstrophied bladder), urethral plate, and penis. **B**, Coronal view showing exstrophied bladder, penis, scrotum, and testes. **C**, Sagittal magnetic resonance image showing same fetus at 21 weeks' gestational age. Note lower abdominal wall, bladder, and penis.

an elephant trunk–like image of the protruding bowel and/or hemi-vertebrae (Hamada et al, 1999; Wax et al, 2008). Prenatal MRI can be used to help confirm the prenatal diagnosis of OEIS (Calvo-Garcia et al, 2013).

The differential diagnosis in the setting of a fetus with an abdominal wall mass includes omphalocele, gastroschisis, bladder exstrophy, and cloacal exstrophy. The last two diagnoses would be entertained when nonvisualization of the urinary bladder is also noted. A study of 41 cases involving fetal abdominal wall mass from the database of the Centre of Fetal Care at Queen Charlotte's and Chelsea Hospital in London from 2000 to 2005 revealed that 25 cases were omphalocele (61%), 9 were gastroschisis (22%), 6 were body stalk anomaly (15%), and 1 case was cloacal exstrophy (2%). Seventeen cases (41%) were associated with other major malformations (Arnaoutoglou et al, 2008).

Cloacal Malformation

Abnormal early development in the fetus may result in lack of separation of the urinary, reproductive, and intestinal tracts, causing persistent cloaca (also known as *cloaca* or *cloacal malformation*) in the female. Direct communication of these three tracts deep to the skin surface results in single perineal opening. Persistent cloaca should be considered in any female fetus with hydronephrosis and a large cystic mass arising from the

pelvis as assessed by ultrasonography and/or MRI (Cilento et al, 1994; Suzumori et al, 2009). Chaubal and colleagues (2003) found calcified meconium to be an important sign in the prenatal sonographic diagnosis of cloacal malformation. Other authors have found that the prenatal ultrasound and MRI findings of fetal ascites, multicystic pelvic mass, bilateral hydronephrosis, and oligohydramnios are highly suggestive of the cloacal malformations associated with meconium peritonitis (Shono et al, 2007; Winkler et al, 2012).

Similar to the fetus shown in Figure 124-15, Liu and colleagues reported MRI findings of hydrocolpos with septate vagina and massive urinary ascites caused by cloacal malformation (Liu and Chen, 2009), and prenatal diagnosis of cloaca associated with esophageal atresia and tracheoesophageal fistula has also been reported (Mori et al, 2007). When present in the fetus with cloaca, urinary ascites develops from retrograde flow of urine from bladder into vagina(s), passing through cervix, uterus, and finally fallopian tube(s). The clinician should be suspicious of associated esophageal atresia and tracheoesophageal fistula with the finding of polyhydramnios in the fetus with suspected cloaca.

As with fetal diagnosis of other complex malformations, prenatal diagnosis of cloaca allows for parental counseling and planning of the delivery at a tertiary center that is well equipped with a neonatal intensive care unit and pediatric surgical and urologic expertise (Warne et al, 2002; Suzumori et al, 2009).

Figure 124-14. Appearance of cloacal exstrophy on imaging of a 19-week gestational age male fetus. **A**, Transverse ultrasound image through lower abdomen showing abdominal wall mass and consistent nonvisualization of the urinary bladder. **B**, Sagittal ultrasound view showing umbilical blood flow and lower abdominal wall mass immediately caudal to the umbilicus. **C**, Transverse magnetic resonance image showing omphalocele with liver and dilated distal left ureter. **D**, Sagittal magnetic resonance image with omphalocele, ureter, and terminal myelocystocele evident.

Congenital Adrenal Hyperplasia

CAH caused by deficiency of 21-hydroxylase is a disorder of the adrenal cortex characterized by cortisol deficiency, with or without aldosterone deficiency, and androgen excess. The severe classic form occurs in 1 in 15,000 births worldwide, and the mild nonclassic form is a common cause of hyperandrogenism. Neonatal screening for CAH and gene-specific prenatal diagnosis are now possible (Merke and Bornstein, 2005).

Reisch and colleagues recently reported the prenatal diagnosis of CAH caused by P450 oxidoreductase deficiency (autosomal recessive inheritance of CAH) as early as gestational week 12 by profiling maternal urine for steroid metabolite excretion. They identified significantly elevated levels of steroids of fetal origin (pregnenolone metabolite epiallopregnanediol and the androgen

metabolite androsterone) with concurrent lower values of estriol in maternal urine. Of the 20 patients, only 5 had evidence of prenatal morphologic features of CAH on ultrasonography (Reisch et al, 2013). Although the accuracy and usefulness of cell-free fetal DNA used prenatally to identify CAH remain unclear, further advances in these technologies may provide newer methods for noninvasive and highly accurate prenatal diagnosis of CAH (Colmant et al, 2013).

Clinical management of patients with CAH involves treating hormonal deficiencies, addressing issues related to genital ambiguity, avoiding morbidities, and communicating with the family about the risk of CAH in other members. Screening for CAH can reduce adrenal crises, avoid incorrect sex assignments, lower mortality (especially in males), and avoid inappropriate somatic growth and precocious puberty (Speiser, 2007).

Figure 124-15. Imaging of a female fetus at 30 weeks' gestational age with cloaca. **A**, Transverse ultrasound view of abdomen showing dilated duplicate vagina, urinary bladder, and urinary ascites consistent with cloaca. **B**, Sagittal ultrasound image showing bladder, markedly distended vagina, kidney with mild hydronephrosis, and urinary ascites outlining bowel and liver. **C**, Coronal magnetic resonance image showing duplicate vagina and urinary ascites. **D**, Sagittal magnetic resonance image of bladder, distended vagina, cervix, uterus, and intra-abdominal organs outlined by urinary ascites.

The most common form of CAH is 21-hydroxylase deficiency (21-OHD). In its severe form, 21-OHD causes prenatal virilization of external female genitalia. Through molecular genetic analysis of fetal DNA, defects in 21-OH synthesis can be diagnosed in utero. Genital ambiguity in females can be reduced or eliminated with prenatal dexamethasone treatment, which successfully

suppresses fetal androgen production. Current data from large human studies show that prenatal diagnosis and treatment are safe in the short term for both the fetus and the mother. Preliminary data from long-term studies support these results (Nimkarn and New, 2009). Nimkarn and New (2009) also reported safety over the long term, but recommend that all subjects exposed to

Figure 124-16. Ultrasound image of megalourethra in a male fetus at 15 weeks' gestational age. **A**, Sagittal view of dilated penile urethra. **B**, Transverse view showing thick-walled bladder and dilated posterior urethra in perineum.

dexamethasone treatment during fetal life have all aspects of their development followed closely. In a recent report of standardized cognitive function testing, CAH-affected girls treated with dexamethasone prenatally appeared to have better cognitive function than untreated CAH-affected girls. However, CAH-unaffected girls treated prenatally with dexamethasone had worse performance in cognitive testing. Cessation of prenatal treatment should stop as soon as possible once the diagnosis has been excluded (Maryniak et al, 2014).

Megalourethra and Prune-Belly Syndrome Association

Congenital megalourethra is a rare genital anomaly characterized by dilatation of the penile urethra with or without evidence of proximal or distal urethral obstruction (Fig. 124-16). Reports of the prenatal diagnosis of this condition in the literature are limited, but most note an overall poor perinatal outcome secondary to pulmonary hypoplasia and poor renal function (Sepulveda et al, 2005). In a recent report of 10 cases identified in a retrospective review, 4 of 10 either were terminated or died in the newborn period (Amsalem et al, 2011). Only 3 of the 10 had normal renal function beyond the newborn period. It is interesting to note that 2 of the 10 had concomitant anal atresia. There have been reports of spontaneous resolution (Nijagal et al, 2004). Some authors have reported cases with prune-belly-like features (Fisk et al, 1990; Wu et al, 1995). The clinician must also consider posterior urethral valves in the differential diagnosis when a dilated urethra is identified in a male fetus.

Myelomeningocele

Prenatal screening with α -fetoprotein (AFP) and ultrasonography has allowed the prenatal diagnosis of neural tube defects (NTDs) in current obstetric care, and the finding of open NTDs in a fetus has been considered an indication for potential in utero surgical treatment. D'Addario and colleagues (2008) evaluated the diagnostic accuracy of ultrasonographic signs that may be looked for in fetuses with NTDs. They confirmed the usefulness of evaluation of the posterior fossa in the diagnosis of NTDs, particularly in cases of small spinal defects that may be missed at ultrasound evaluation, noting that in 49 fetuses reviewed a small cerebellum was found in 96%, an effaced cisterna magna in 93%, and a small posterior fossa in 96%. Ventriculomegaly was present in 40 of 49 (82%) cases. With the finding of these associated features the NTD was identified in all but one fetus. Miller and colleagues (2006) studied the impact of prenatal MRI on diagnosis and neurosurgical treatment. Between 1999 and 2003 they reviewed 320 fetal MRI

studies that were performed at a single institution. Twenty-four fetuses were found to have central nervous system abnormalities. The diagnoses included spinal anomalies (e.g., scoliosis, myelomeningocele, and closed spinal dysraphism) and brain anomalies (e.g., ventriculomegaly with or without hemorrhage, intracranial cyst, craniosynostosis, and encephalocele). Fourteen of the 24 fetuses underwent surgery based on findings of prenatal MRI, and in 7 cases the pregnancy was terminated.

It is interesting to note that quantification of amniotic fluid glial fibrillary acidic protein (AF-GFAP) was recently reported as a potential biomarker of NTDs (Lopez et al, 2013). Enzyme-linked immunosorbent assay (ELISA) of AF-GFAP was conducted in 138 cases of NTDs, 70 healthy controls, and 27 AFP false-positive samples, and AF-GFAP levels were found to be elevated in 99.1% of open NTDs. AF-GFAP was negative in all cases of closed NTDs. Although highly preliminary, these data are very intriguing with regard to a potential additional biomarker for NTDs. Further studies multiplexing this marker and others (AFP, ultrasound findings) will be necessary to determine the most clinically effective biomarker panel.

Currently there is evidence that prenatal repair of myelomeningocele improves neurologic function. Myelomeningocele is the first nonlethal disease under consideration for fetal surgery (Adzick et al, 2011). However, as with any fetal intervention, the potential improvements in outcome must be balanced with maternal safety and well-being, in addition to the safety and well-being of the fetus (Hirose and Farmer, 2009). The randomized Management of Myelomeningocele Study (MOMS) clinical trial examined the efficacy of open fetal myelomeningocele repair as compared with postnatal repair (Adzick et al, 2011). In this study and others, there appeared to be an improvement in the need for neonatal shunting and motor outcomes at 30 months, but not without maternal and fetal risk (Danzer et al, 2009). Specifically, in the 183 randomized patients, significant differences were noted in shunt rates (40% fetal vs. 82% postnatal), motor function and anatomic level (32% of fetuses vs. 12% of postnatal children with two or more spinal levels better), rates of independent ambulation without orthotics (42% fetal vs. 21% postnatal), and Bailey Psychomotor Development Index scores (64.0 vs. 58.3) (Adzick et al, 2011). Further long-term comparative evaluation is necessary to determine the overall benefits of the fetal intervention.

As for postnatal bladder function after in utero repair, a study of 11 patients who underwent open in utero repair and 22 who underwent postnatal repair did not demonstrate any difference in the need for clean intermittent catheterization, incontinence between catheterizations, or anticholinergic or antibiotic use (Lee et al, 2012). In addition, urodynamic parameters including bladder capacity, detrusor pressure at capacity, detrusor overactivity, and the

presence of detrusor sphincter dyssynergia were not significantly different between the groups.

Renal Mass

Although congenital mesoblastic nephroma (CMN) is a rare benign congenital renal tumor, it is the most common solid renal tumor in the newborn period. Typically the prenatal diagnosis of CMN has been made on the basis of the findings of sonography in the third trimester. CMN is typically described as a hypoechoic homogeneous or heterogeneous solid renal mass with an echogenic rim that is not often well defined (Geller et al, 1997; Chen et al, 2003). A vascular ring sign—an anechoic ring surrounding the tumor—has been described for CMN (Kelner et al, 2003). Sonographic findings of CMN and Wilms tumor are similar, and absolute distinction often can be made only pathologically. Recently there have been a few reported cases of CMN identified by MRI (Chen et al, 2003; Linam et al, 2010; Ko et al, 2013). MRI may help delineate CMN from other masses and provide additional information with respect to adjacent structures.

Rhabdoid tumor of the kidney is relatively rare but a highly lethal malignancy of infancy. Prenatal detection of a renal rhabdoid tumor with mesoblastic components has been achieved in a 27-week fetus (Fuchs et al, 2004). The tumor appeared as a large mass in the left renal area with concomitant massive polyhydramnios. Ultrasound features alone did not distinguish the tumor from a benign lesion, but aggressive growth of the tumor indicated malignancy. Amniotic fluid cytology was performed but failed to confirm the diagnosis.

Leclair and colleagues (2005) reviewed outcome in 28 patients with prenatally diagnosed renal tumors from 20 institutions. The diagnosis was CMN in 26 patients and Wilms tumor in 2 patients. One or more complications were identified in 20 of the 28 patients (71%) during the perinatal period. Polyhydramnios was observed in 11 fetuses (39%), 2 had hydrops fetalis, and 7 developed acute fetal distress necessitating emergency cesarean section, of which 1 died in utero before delivery. Median gestational age of the 27 neonates born alive was 35 weeks (range 29 to 39), including 13 of the 28 patients reviewed (46%) who were born before term. Complications at birth included hemodynamic instability in 3 neonates, respiratory distress syndrome in 8 (30%), and hypertension in 6 (22%). Surgical complications occurred in 7 patients (26%), including tumor rupture in 1 and intraoperative bleeding with postoperative death in 1. At median follow-up of 42 months, 26 of the 27 children were in complete remission. Leclair and colleagues concluded that prenatally diagnosed renal tumors have an excellent oncologic outcome but a high risk of perinatal complications. Prenatal diagnosis should allow planning the delivery at a pediatric tertiary care center to avoid a potentially life-threatening condition in early neonatal life.

Although Beckwith-Wiedemann syndrome (BWS) and other overgrowth syndromes are difficult to diagnose prenatally, the presence of renal enlargement and other findings suggestive of overgrowth should raise the suspicion of these potential diagnoses. A prenatal diagnosis can be suggested by ultrasound; particularly with BWS, sonographic and MRI findings including macrosomia, polyhydramnios, omphalocele, macroglossia, hepatomegaly, and renal enlargement are helpful in distinguishing the condition (Vora and Bianchi, 2009; Storm et al, 2011). If an overgrowth syndrome is suspected, further genetic analysis can be offered (Vora and Bianchi, 2009). Other overgrowth syndromes to consider include Pallister-Killian, Sotos, Perlman, and Simpson-Golabi-Beckel syndromes, but these typically involve other systems not involved in BWS (Vora and Bianchi, 2009).

Renal Vein Thrombosis

Renal vein thrombosis (RVT) is a rare event. The incidence varies from 0.5 per 1000 admissions in neonatal intensive care units to 0.5% in autopsy findings. Antenatal ultrasound findings include an enlarged kidney, loss of corticomedullary differentiation, and

Figure 124-17. Antenatal ultrasound image at 38 weeks' gestation demonstrates an enlarged left hyperechoic kidney with loss of corticomedullary differentiation.

Figure 124-18. Antenatal ultrasound image at 36 weeks' gestation shows a left renal vein thrombosis extending into the inferior vena cava. Note the mural calcification of the inferior vena cava.

branching hyperechoic vessels (Fig. 124-17). Often, an inferior vena cava thrombus can be seen with decreased or no flow in the affected renal vein (Fig. 124-18). Diallo and colleagues (1998) reported a case of RVT that was diagnosed at 34 weeks' gestation by ultrasonography in a fetus showing signs of fetal distress. The typical pattern of renal enlargement, loss of corticomedullary differentiation, echogenic streaks, lack of definition of renal sinus echoes, and loss of venous flow in the affected kidney by Doppler imaging was observed. After cesarean section, full recovery at 1 week and a normal evolution at 1 month of life were reported.

Adrenal Mass

The differential diagnosis of prenatally diagnosed adrenal masses includes neuroblastoma, adrenal hemorrhage, adrenal and cortical renal cysts, adrenal adenoma and carcinoma, subdiaphragmatic pulmonary sequestration, BWS, duplication of the renal system, Wilms tumors, CMN, and mesenteric and enteric duplication cysts. According to Sherer and colleagues, the worldwide annual incidence of childhood adrenal cortical neoplasms ranges from 0.30 to 0.38 per 1 million children younger than 15 years. These neoplasms are even more unusual among infants, suggesting spontaneous resolution in some lesions, with only 23 cases reported in the literature (Sherer et al, 2008).

Curtis and colleagues (Sherer et al, 2008) developed an algorithm that facilitates the correct diagnosis of the suprarenal masses, subdiaphragmatic extralobar pulmonary sequestration, and neuroblastoma, allowing the correct diagnosis to be made prenatally in 95% of patients. Based on a literature review, the authors identified distinguishing features of the two lesions and created an algorithm on the basis of these distinctions. Typical findings on prenatal ultrasonography for subdiaphragmatic extralobar pulmonary sequestration include an echogenic mass that is left sided and can often be identified during the second trimester. Neuroblastoma is most often cystic, right sided, and identified in the third trimester.

Fang and colleagues (1999) reported adrenal hemorrhage confirmed in a neonate after first detection by ultrasonography at 21 weeks' gestational age. The echogenic right suprarenal mass became larger and hypoechoic on follow-up postnatal ultrasonography. With difficulty differentiating the lesion from cystic neuroblastoma, the authors performed a surgical exploration when the patient was 2 months old, and adrenal hemorrhage was confirmed, thus suggesting that adrenal hemorrhage can occur as early as the second trimester. Characteristic imaging features on ultrasonography, color Doppler imaging, and MRI help differentiate adrenal hemorrhage from neuroblastoma (Gocmen et al, 2005).

KEY POINTS: SPECIFIC DIAGNOSES

- Antenatal ultrasound findings suggestive of UPJ obstruction include dilation of the renal pelvis and collecting system with no evidence of ureteral dilation.
- The findings of MCDK include multiple noncommunicating cysts, minimal or absent renal parenchyma, and the absence of a central large cyst.
- Antenatal detection of ARPKD often is based on bilaterally enlarged echogenic kidneys without obvious renal cystic disease. Concomitant hepatobiliary dilatation or oligohydramnios further suggests the disease.
- Duplication anomalies are often recognized on the basis of upper pole hydroureteronephrosis in association with either an obstructing ureterocele or an ectopic ureter.
- Very large ureteroceles can be mistaken for the bladder.
- VUR cannot be definitively diagnosed on antenatal ultrasonography, although intermittent or varying degrees of hydronephrosis or a hydroureter is suggestive of the diagnosis.
- Antenatal findings of posterior urethral valves include bilateral hydroureteronephrosis, a thick-walled bladder with dilated posterior urethra, renal dysplasia, and/or perinephric urinomas and urinary ascites.
- Fetal characteristics of bladder exstrophy include nonvisualization of the fetal bladder, lower abdominal wall mass immediately inferior to a low-lying umbilicus, and diminutive genitalia.
- Antenatal findings of exstrophy in combination with omphalocele and with kidney and lumbosacral spine abnormalities suggest cloacal exstrophy.
- Hydronephrosis and a large cystic mass arising from the pelvis in a female fetus suggest a persistent cloaca.

ANTENATAL MANAGEMENT OF FETAL UROPATHIES

Up to 3% of all pregnancies involve fetal urinary tract anomalies. The vast majority of anomalies are associated with hydronephrosis. Severe obstruction that might warrant antenatal intervention comprises less than 5% of all detected anomalies.

The primary role for the perinatal urologist is to provide education and counseling for prospective parents in an objective manner. Often the patient is referred to the urologist after much information has been provided to the family. The counseling urol-

ogist should (1) provide reassurance and dispel misconceptions, (2) provide a reasonable differential diagnosis, (3) supply information regarding the natural history of the disease, (4) give antenatal recommendations, and (5) provide a postnatal management plan, which will be discussed further. The need for continued antenatal evaluation is debatable and unclear, particularly with mid- and late-trimester mild and moderate hydronephrosis. In the setting of severe unilateral or bilateral hydronephrosis, more regular follow-up is reasonable. If there is a suspicion of bladder outlet obstruction, regular follow-up is needed. In addition to normal fetal growth parameters, amniotic fluid volume, renal appearance (echogenicity, degree of hydronephrosis, cystic changes), and extrarenal fluid collections should be monitored closely.

Rationale and Indications for Fetal Intervention

Overall, the need to consider in utero intervention for obstruction is uncommon. However, in the specific cases in which it should be considered, the rationale for antenatal treatment of hydronephrosis is to maximize development of pulmonary and renal function. These two aspects of fetal development are closely linked because urine comprises more than 90% of amniotic fluid volume by the 16th week of gestation and because oligohydramnios during the second trimester is often associated with a lethal postnatal outcome secondary to pulmonary hypoplasia.

Before prenatal surgical intervention for obstructive uropathy, it is critical to assess the risk-benefit ratio. The time of onset of oligohydramnios has been shown to be an important determinant of outcome (Mahony et al, 1985; Mandell et al, 1992b). In fetuses in which adequate amniotic fluid was documented at up to 30 weeks' gestation in association with a urologic abnormality, pulmonary outcomes were satisfactory and postnatal clinical problems were related to renal disease. Therefore, in the setting of late-onset oligohydramnios there appears to be limited usefulness of urinary tract decompression or early delivery for pulmonary reasons. It is also unclear whether early delivery to permit earlier postnatal urinary decompression is beneficial. If early delivery is considered, maternal corticosteroid administration for pulmonary development should be considered. Neonatology colleagues should also be involved in any early delivery decision process.

The most widely accepted indicator of salvageable renal function is analysis of fetal urine. When the urinary sodium value is less than 100 mg/dL, urine chloride value is less than 110 mmol/L, and urine osmolality is less than 200 mOsm/dL, renal function appears to be salvageable with in utero intervention (Table 124-4).

TABLE 124-4 Indications and Conditions for in Utero Urinary Decompression

INDICES	COMMENT
Evidence of bladder outlet obstruction	Dilated bladder, hydroureteronephrosis
Normal karyotype	By amniocentesis
No systemic anomalies	For example, central nervous system, cardiovascular
Male fetus	—
Singleton	—
Oligohydramnios	Early onset: <25 wk
Noncystic kidneys	Degree of echogenicity is subjective; cysts are poor prognostic sign
Favorable urinary indices	Na <100 mg/dL, Cl <110 mg/dL, osmolality <210 mOsm/dL; or serial samplings trending toward normal; β_2 microglobulin <10-20 mg/L
Informed consent	Risks of partial treatment must be included

(Glick et al, 1985). The accuracy of these predictors has been challenged (Wilkins et al, 1987; Elder et al, 1990) and, more recently, serial aspirations of fetal urine have been reported to yield more valuable results (Johnson et al, 1995). Guez and coworkers (1996) published a report regarding 10 fetuses who underwent multiple urine samplings and in whom severe obstruction reduced sodium and calcium reabsorption. The researchers concluded that fetal urinary chemistries were reasonably predictive of severe but not moderate postnatal renal impairment.

Other investigators have suggested the use of fetal urinary β_2 microglobulin as an indicator of tubular damage. In normal postnatal kidneys, more than 99.9% of β_2 microglobulin is reabsorbed and metabolized in the proximal tubules; in postnatal renal disease with damage to this area, β_2 microglobulin is excreted in the urine. If urinary β_2 microglobulin is reflective of prenatal renal damage, including this parameter, poor renal outcome has been predicted with a specificity of 83% and sensitivity of 80% (Tassis et al, 1996). However, a 2007 systematic review of fetal urine as a predictor of postnatal renal outcome demonstrated that there was insufficient evidence to support β_2 microglobulin as a predictor of renal function (Morris et al, 2007). From 23 studies the researchers identified 572 women; the two most accurate fetal urine tests were urinary calcium and sodium. In this analysis, β_2 microglobulin was found to be less accurate (Morris et al, 2007).

Findings on antenatal ultrasound have also been examined with regard to prediction of long-term postnatal renal function. In a systematic review of 13 articles encompassing 251 women, oligohydramnios and the appearance of the renal cortex (increased echogenicity or cystic changes) at the diagnosis of lower urinary tract obstruction were the best factors to predict poor renal function (defined as creatinine >1.2 mg/dL) (Morris et al, 2009). In this particular study, gestational age at diagnosis (<24 weeks) was not predictive of renal function, which may reflect the inherent variability of the available literature.

Clinical Experience

The ability to diagnose severe prenatal hydronephrosis and advances in fetal intervention have helped develop prenatal surgery for obstructive uropathy. Harrison and colleagues (1982) described the initial report of fetal surgery in a 21-week-old fetus with bilateral hydronephrosis secondary to posterior urethral valves. After the 1986 report of the International Fetal Surgery Registry in which outcomes did not seem to justify risk, a de facto moratorium on in utero urinary tract shunting evolved (Manning et al, 1986).

More recently, with improved technology and renewed interest in fetal shunting, most cases have been reported by a small number of highly specialized centers actively engaged in prenatal surgery. The initial method of decompression with open surgery has largely been replaced by in utero shunt placement. The technique of shunt placement emerged from the University of California, San Francisco group (Harrison et al, 1982). The shunt is placed under ultrasound guidance using a Seldinger technique through a trocar (Fig. 124-19). Current practice uses the Rodeck shunt, which lies flat against the abdomen to minimize shunt dislodgment. Complications include shunt dislodgment and bowel herniation (Robitiaux et al, 1991). Amnioinfusion may be needed to improve visualization for shunt placement; however, this may lead to excessive fetal movement. Occasionally the fetus needs to be paralyzed for accurate placement. Very large bladders may cause the shunt to be placed too high in the abdomen, resulting in dislodgment from the bladder after it decompresses.

Fetoscopic methods for direct intervention to provide prolonged bladder drainage have also been explored (Quintero et al, 2000; Clifton et al, 2008; Sago et al, 2008; Ruano et al, 2010, 2014). The proposed advantage of fetoscopic intervention over vesicoamniotic shunting is to improve drainage and to restore normal cycling of the bladder. There are no studies to determine if this method of decompression is adequate in the face of significant prenatal bladder dysfunction. Furthermore, fetoscopic intervention also introduces the additional potential for iatrogenic injury to the urethra, bladder

Figure 124-19. Diagram showing technique of fetal vesicoamniotic shunt placement. The fetal bladder is initially reached with needle, and a large-bore introducing sheath is passed into the bladder (A). Within this sheath, the shunt is passed (B and C). It is a double-pigtail shunt with holes at each end allowing free drainage between the bladder and amniotic space (D). (From Peters CA. Surgical management of fetal uropathies. In: Marshall FF, editor. Textbook of operative urology. Philadelphia: Saunders; 1996. p. 1063.)

neck, or external urethral sphincter. In a systematic review of the literature, 4 papers totaling 63 patients identified that fetal cystoscopy as compared with vesicoamniotic shunts had no significant improvement in perinatal survival (Morris et al, 2011). Overall, experience with fetoscopic or endoscopic valve ablation is currently at the case report and experimental levels, and long-term outcome data are unknown.

The indications and contraindications for intervention in prenatal obstructive uropathy are outlined in Table 124-4. Currently, serial bladder sampling over 3 days has been used to help determine if the fetus is a viable candidate. The serial nature of the procedure allows one to see the subsequent trend of urine osmolality and electrolyte composition as a reflection of fetal kidney response (Johnson et al, 1995). The principal reason for considering vesicoamniotic shunting is to prevent early neonatal pulmonary insufficiency and death. The risks that one accepts with intervention include induction of premature labor, perforation of fetal bowel and bladder, fetal loss, and fetal and/or maternal hemorrhage and infection.

More recently, the ability to influence renal outcome in male patients with posterior urethral valves but without oligohydramnios has been suggested as a possible indication for in utero intervention. In this setting the principal goal of intervention is not to prevent pulmonary hypoplasia and deaths but to prevent or delay end-stage renal failure. Although some reports have shown promise in the ability to distinguish those fetuses with likely early renal failure from those with later-onset failure, the specificity and accuracy of methods using a combination of ultrasound and urinary chemistries (sodium, β_2 microglobulin, and calcium) has not been well defined (Muller et al, 1993; Clautice-Engle et al, 1995; Domergues et al, 2000). In summary, precise identification of those

situations in which intervention may benefit the fetus with obstructive uropathy remains unclear.

Clinical Outcomes

To date, the reported long-term outcomes of antenatal intervention for severe obstructive uropathy (e.g., posterior urethral valves, prune-belly syndrome, urethral atresia) are mixed (Crombleholme et al, 1990; Johnson et al, 1994; Coplen et al, 1996; Freedman et al, 1999; Holmes et al, 2001; McLorie et al, 2001; Clark et al, 2003; Biard et al, 2005; Salam, 2006; Ethun et al, 2013; Tonni et al, 2013). Significant variability in patient selection and assessment of outcome within these studies has limited the ability to determine if prenatal intervention has altered the postnatal course. A large systematic review of the prenatal intervention for obstructive uropathy showed a statistically significant perinatal survival advantage with shunting (Clark et al, 2003); however, lack of randomization of patient selection in the trials reviewed may have biased the results. Of the studies that have reported long-term outcomes of in utero vesicoamniotic shunting, many of the children have renal insufficiency (57%) and growth impairment (86%) (Freedman et al, 1999; Holmes et al, 2001; Biard et al, 2005). Biard and associates (2005) reported on long-term follow-up (5.8 years) of patients who survived in utero shunting. These researchers noted acceptable renal function in 44%, mild impairment in 22%, and renal failure in 33%. Patients with prune-belly syndrome had the best renal outcome (57%), followed by those with posterior urethral valves (43%), and then urethral atresia (25%).

The European-based multicenter randomized clinical trial PLUTO (Percutaneous Shunting for Lower Urinary Tract Obstruction) was recently completed (Morris et al, 2013). The initial goal was to enroll 150 singleton pregnancies with ultrasound evidence of lower urinary tract obstruction to evaluate the safety and effectiveness of vesicoamniotic shunting as compared with conservative management. The study was stopped early because of poor enrollment; only 31 patients were enrolled and randomized (16 vesicoamniotic shunt patients and 15 controls). In the vesicoamniotic shunt group, there were 12 live births and 4 postnatal deaths at 28 days; and in the control group there were 12 live births and 8 postnatal deaths. All postnatal deaths were from pulmonary hypoplasia. Although underpowered, the study demonstrated a nonsignificant increase in survival in the vesicoamniotic shunt group. Consistent with the results of the systematic review of existing prenatal intervention data, there was minimal likelihood of surviving with long-term normal renal function.

Overall, it appears that select in utero intervention for the appropriate patient may reduce the risk of neonatal mortality. Improvement in renal function does not appear to be likely. Without doubt, more sensitive and specific markers to better identify which fetus will benefit from in utero shunting need to be defined.

KEY POINTS: ANTENATAL MANAGEMENT OF FETAL UROPATHIES

- Up to 3% of all pregnancies involve a urinary tract anomaly.
- The primary role for the perinatal urologist is to provide education and counseling for prospective parents in an objective manner.
- The need to consider in utero intervention for obstruction is uncommon.

POSTNATAL MANAGEMENT OF ANTENATALLY DETECTED UROLOGIC RENAL ABNORMALITIES

A child with a prenatal diagnosis of a urologic renal abnormality such as ANH should be carefully evaluated and followed by a pedi-

atric urologist from birth. The vast majority of these children appear entirely healthy and in the absence of prenatal ultrasound findings would not have any indications for regular urologic follow-up. Parental anxiety is common and should be addressed directly with prenatal counseling and education.

Unilateral Hydronephrosis

The presence of prenatally detected unilateral dilation of the kidney warrants postnatal ultrasound evaluation in a timely but nonurgent fashion (3 to 8 weeks of life) (Claudice-Engle et al, 1995). The most common diagnoses associated with this finding are UPJ obstruction, VUR, and UVJ obstruction and megaureter. Early ultrasound evaluation is unlikely to miss a significant abnormality. Normal postnatal ultrasound examination findings indicate that obstructive uropathy is not present; however, normal findings do not indicate whether the child has VUR (Tibballs and De Bruyn, 1996). It is important to keep in mind that a postnatal ultrasound evaluation performed within the first 48 hours of life may not yet demonstrate hydronephrosis or may underestimate the degree of hydronephrosis secondary to physiologic oliguria in the newborn.

The decision to obtain a voiding cystourethrogram (VCUG) or initiate prophylactic antibiotics in the newborn period is unclear. Although some groups advocate postnatal VCUG in any child with a history of ANH, others have questioned the value of this approach (Yerkes et al, 1999). Various guidelines and recommendations have been proposed with regard to VCUG usage, but no definitive studies have rigorously studied the likelihood of VUR based on consistent ultrasound findings or other clinical characteristics. The current trend in management of ANH minimizes postnatal prophylactic antibiotics and testing for VUR in cases of resolved ANH or in mild to moderate cases of persistent postnatal ANH owing to a lack of evidence for a benefit to screening (Nguyen et al, 2010).

In general, infants with severe ANH should be placed on a prophylactic antibiotic (amoxicillin, 10 to 25 mg/kg/day) and undergo VCUG. Severe ANH may be associated with an increased risk of febrile urinary tract infection and possibly may indicate a higher grade of VUR (Song et al, 2007; Grazioli et al, 2010). As for mild ANH, a prospective study of 192 infants with ANH noted that the majority of patients with mild ANH had no significant events during infancy (Coelho et al, 2007). In another study, female infants with a history of ANH and postnatal uropathy had a higher risk of febrile urinary tract infection (Coelho et al, 2008). Regardless, no appropriate prospective studies with coordinated and comprehensive postnatal follow-up have examined this question in a rigorous fashion to provide consensus guidelines (Lee et al, 2006; van Eerde et al, 2007; Skoog et al, 2010).

At our institution, children with moderate or severe ANH are placed on a prophylactic antibiotic at birth. These children undergo renal bladder ultrasonography and VCUG postnatally. Diuretic renography is reserved for those with persistent moderate or severe postnatal hydronephrosis not related to VUR. Infants with persistent mild hydronephrosis (unilateral or bilateral) on serial ultrasound evaluation or no postnatal hydronephrosis are observed and followed clinically. Infants with a significant degree of antenatal or postnatal ureteral dilation undergo ultrasonography, VCUG, and possibly diuretic renography (with technetium-99m mercaptoacetylglutrylglycine) if clinically indicated.

Perhaps the most challenging aspect of managing ANH is determining if and when postnatal surgical correction for obstruction is appropriate (Ransley et al, 1990). Some have suggested that regardless of the degree of ANH, moderate or severe postnatal hydronephrosis with evidence of decreased renal function should be an indication for surgical intervention (Chertin et al, 2006). Despite the improved anatomic detail afforded by real-time ultrasonography and the increasing experience with functional nuclear medicine studies, no radiographic or clinical gold standard for physiologically significant obstruction exists. Over time, hydronephrosis has been seen to improve whereas other kidneys appear to lose function. The natural history of ANH is not clearly defined.

The debate over the appropriate management of infants with unilateral ANH continues and may ultimately be determined by a combination of epidemiologic, radiographic, and new innovative biomarker discoveries. More accurate and reproducible prenatal and postnatal radiographic documentation of the degree of hydronephrosis and function combined with appropriate natural history data are needed to better categorize these infants. Finally, new serum or urine biomarkers indicative of ongoing renal damage will be critical in helping to further define which infants are truly at risk.

Bilateral Hydronephrosis

Infants with bilateral hydronephrosis may have posterior urethral valves, bilateral VUR, bilateral UPJ or UVJ obstruction, or a combination of these findings. **For the child with bilateral hydronephrosis suggestive of bladder outlet obstruction, an ultrasound evaluation and VCUG should be performed promptly.** In boys, the presence of posterior urethral valves is the most important diagnosis to be ruled out. In girls, an obstructing ectopic ureterocele would be the most likely cause of bladder outlet obstruction. In the event that an obstructive lesion is discovered, it should be corrected promptly. For children with suspected lower urinary tract obstruction (e.g., posterior urethral valves), prompt bladder decompression and antibiotic prophylaxis (amoxicillin 10 to 25 mg/kg/day) should be initiated before radiographic intervention.

Renal Agenesis, Renal Ectopia, and Unilateral Multicystic Dysplastic Kidney

Infants born with solitary kidneys (renal agenesis), renal ectopia, or unilateral multicystic dysplasia should be evaluated postnatally by ultrasonography. The need for a postnatal VCUG is controversial. Functional studies such as with dimercaptosuccinic acid (DMSA) are occasionally needed to confirm the diagnosis but may not be needed in all children. The need for further screening with VCUG is controversial. It has been reported that of infants with a solitary kidney, 30% have VUR, 11% UPJ obstruction, and 7% UVJ obstruction (Atiyeh et al, 1993; Cascio et al, 1999). Similarly, those with renal ectopia (simple or crossed fused ectopia) may also be at risk for VUR in the ectopic or contralateral kidney (30%) (Gleason et al, 1994; Guarino et al, 2004; Arena et al, 2007). However, other researchers report a very low incidence of associated urologic anomalies and do not recommend screening (Calisti et al, 2008).

An MCDK is primarily unilateral, isolated, and associated with a good prognosis. If at birth the ultrasound findings are not absolutely diagnostic of a classic MCDK, a DMSA study can be used to confirm the diagnosis with the absence of uptake. Patients with MCDK are often thought to be similar to those born with a solitary kidney. In addition, patients with MCDK have a reported increased frequency of VUR and UPJ obstruction in the contralateral normal kidney (Kaneko et al, 1995; Miller et al, 2004) but use of routine screening by VCUG remains controversial (Ismaili et al, 2005).

KEY POINTS: POSTNATAL MANAGEMENT OF ANTENATALLY DETECTED UROLOGIC RENAL ABNORMALITIES

- Infants with antenatal unilateral hydronephrosis should undergo an ultrasound evaluation 3 to 8 weeks after birth.
- Postnatal ultrasonography performed within 48 hours of birth may underestimate the degree of hydronephrosis.
- An infant with bilateral hydronephrosis consistent with bladder outlet obstruction should undergo ultrasound evaluation and VCUG promptly.

TABLE 124-5 Presenting Signs of Neonatal Urologic Emergencies

SIGN	ETIOLOGY	EVALUATION
Sepsis	Bladder outlet obstruction	Urine and blood cultures
	Vesicoureteral reflux	Ultrasound
	Megaureter	VCUG
	Ectopic ureter	
	Ureterocele	
	Ureteropelvic junction obstruction	
	Fungal infection with secondary obstruction	
Hematuria	Urinary infection	Urine Culture
	Renal vein thrombosis	VCUG
Hypertension	Renal vein thrombosis	Ultrasound
	Renal artery thrombosis	DMSA studies
Renal mass	Hydronephrosis	Ultrasound
	ARPKD	Computed
	Multicystic dysplastic kidney	tomography,
	Congenital mesoblastic nephroma	DMSA studies,
	Neuroblastoma	magnetic
	Wilms tumor	resonance imaging
Renal failure	Urinary obstruction	Urine culture
	Sepsis	Urine electrolytes
	Renal cortical necrosis	Ultrasound
	Renal dysplasia or agenesis	DMSA, MAG3 scan
Urinary ascites	Urinary obstruction	Ultrasound
		VCUG
Scrotal mass	Neonatal torsion	Examination
	Hydrocele	Ultrasound
	Tumor	

ARPKD, autosomal recessive polycystic kidney disease; DMSA, dimercaptosuccinic acid; MAG3, technetium-99m mercaptoacetyltriglycine; VCUG, voiding cystourethrogram.

NEONATAL UROLOGIC EMERGENCIES

During the neonatal period, various neonatal urologic emergencies can cause diverse signs and symptoms (Table 124-5). A thorough history and examination may identify other associated conditions. Even though many of the conditions may involve an isolated aspect of the urogenital system, the evaluation of the entire genitourinary system is warranted in the context of the overall health and care of the child.

Perineal Mass in a Female

The presence of a protuberant mass in the perineum of a newborn girl should suggest four principal diagnoses. The appearance usually indicates the most likely diagnosis. The most common entity producing this general finding in a newborn is a periurethral cyst. These are whitish in appearance and covered by a delicate but normal epithelium. The urethral meatus is adjacent but uninvolved. Incision and drainage are usually curative. Imperforate hymen with resulting hydrocolpos may arise with a

midline bulging of whitish tissue symmetrically between the labia and behind the urethra. A palpable abdominal mass may be present because of uterine distention, and occasionally hydronephrosis is found on ultrasonography. A separate fluid-filled cavity in the pelvis should be distinguishable and not confused with the bladder. Management of an imperforate hymen is incision and drainage, which is also appropriate for the less common vaginal stenosis. The substance drained is often milky white and may be of surprising volume. Subsequent intervention is seldom needed. **Prolapse of an ectopic ureterocele may have a similar appearance, distinguished by its often edematous, congested, or frankly necrotic appearance. On close examination, it may be seen emerging from the urethra in an eccentric fashion, usually posteriorly. A distended bladder may be palpable. Ultrasonography combined with early filling images on a voiding cystography should provide the diagnosis. Management of the ureterocele is discussed in Chapter 134. Urethral prolapse is uncommon in newborns but may be seen as a circumferential collar of edematous and ecchymotic tissue at the urethral meatus (Lowe et al, 1986). Topical measures such as skin moisturizers, hot compresses, and relief of aggravating factors (urethral catheter, prolonged coughing, or straining) may relieve the prolapse. If tissue necrosis is evident, surgical resection could be considered. Although uncommon in the neonatal period, botryoid sarcomata of the vagina may arise as a protuberant vaginal mass, usually with a distinctive, multilobulated appearance, and a solid pelvic mass may be seen on ultrasonography (Chapter 156).**

Abdominal Mass

The diagnosis of an abdominal mass in a neonate has become greatly simplified with the availability of ultrasound imaging. In many cases the identity of the mass will have been suggested prenatally. **The principal entities to be considered include hydronephrosis, cystic renal disease, adrenal hemorrhage, a dilated bladder, gastrointestinal duplications, and tumor (Hartman and Shochat, 1989; Schwartz and Shaul, 1989; McVicar et al, 1991; Chandler and Gauderer, 2004).** The likelihood of any abdominal mass being of urinary tract origin is high, with more than 60% being hydronephrosis or MCDK (Schwartz and Shaul, 1989). Physical examination should determine the location, size, texture, and mobility of the mass, as well as other abnormalities on examination, including limb, cardiac, and central nervous system findings. Ultrasonography is usually able to identify the organ of origin, the cystic or solid nature of the mass, and the condition of the uninvolved elements of the genitourinary tract and permit a more focused and detailed subsequent evaluation. It cannot be overemphasized that care must be taken to examine the entire abdomen.

Imperforate Anus

Up to 75% of all cases of imperforate anus have associated malformations, with genitourinary and spinal cord anomalies being the most common (Nah et al, 2012). **Prenatally, the presence of imperforate anus may be suggested by punctate calcifications in the intestinal lumen related to formation of meconium calcifications from exposure to urine (Mandell et al, 1992a).** An ultrasound examination and VCUG should be performed at the initial presentation to assess the urinary tract, and to assess the level of the rectourethral or vesical fistula in boys. Ultrasound examination of the spinal cord to assess for spinal cord tethering should be performed in the newborn period before complete ossification of the vertebral column. Initial management is usually a diverting colostomy, which should be constructed using the transverse colon and with separation of the proximal and distal limbs to limit the risk of fecal contamination in boys with a rectourethral fistula. Complications related to the confluence of the gastrointestinal and urinary tracts may occur, including infection and metabolic derangements.

Oligohydramnios, Potter Syndrome, Renal Agenesis

The anatomic features of Potter syndrome include oligohydramnios, limb contractures (particularly clubfeet), and compressed facies with low-set ears. If this syndrome is suspected, immediate ultrasonography permits confirmation of the diagnosis as evidenced by absent or bilaterally dysplastic or cystic kidneys. These children may die from respiratory failure in the first hours of life, although survival for several days has been reported. The role of the urologist is largely one of confirming the diagnosis and providing counseling to parents and staff in these tragic cases. Little specific therapy is available to the urologist.

Single Umbilical Artery

The presence of a single umbilical artery, occurring in about 0.3% to 0.55% of live births, has been associated with an increased incidence of genitourinary anomalies in the past (Vlietinck et al, 1972). Many of these early studies included stillborn fetuses in which the incidence of renal anomalies was about 60% (Thummala et al, 1998). More recent examination of the incidence has suggested that the degree of increase is relatively minimal—about 7.1% for all renal anomalies, including reflux with an incidence of 4.5% (Bourke et al, 1993). These authors recommended routine screening for a single umbilical artery, although the clinical significance of the anomalies identified is unclear. **A meta-analysis of 37 studies of single umbilical arteries indicated that it would require screening of 14 children with a single umbilical artery to identify 1 child with a renal anomaly, and the renal anomalies are typically of minimal significance (Thummala et al, 1998; Deshpande et al, 2009).** The authors did not recommend routine screening. If there is suspicion, a renal ultrasound examination is an adequate screening tool.

Sepsis

In infants with sepsis, a catheterized or suprapubically aspirated urine specimen for culture must be obtained before antibiotic therapy. If pyuria is present, urosepsis should be strongly considered. A screening ultrasound to assess the urinary tract is critical, as many cases of urosepsis include a sonographic abnormality. The most common causes include obstructive uropathy or high grade VUR. A normal ultrasound study does not rule out reflux, and in the presence of urosepsis, VCUG is essential when the patient's condition is stable. This should probably be obtained during the acute hospital admission. Further workup should be tailored to the findings of the initial examinations.

Infant boys with intact foreskins have a higher risk of urosepsis and may not have specific anatomic findings (Wiswell and Hachey, 1993; Schoen et al, 2000). These boys should undergo the usual evaluation with an ultrasound examination and VCUG to rule out obstruction and reflux.

Absence of Voiding

The normal time for the first postnatal void extends to 24 hours, and some healthy children wait even longer (Vuohelainen et al, 2008). The most useful physical finding to determine is whether the bladder is distended. Physical examination may precipitate voiding. Ultrasound examination may be obtained when there has been no void after 24 hours, the bladder is distended, or parental concern is high. Specific findings dictate management. The time to void after circumcision is predictable and depends in part on feeding times. Within 8 hours of circumcision, 75% of breastfed and 100% of formula-fed infants had voided (Narchi and Kulayat, 1998). A common cause of concern is the pinpoint meatus often seen with hypospadias in conjunction with delayed first void. The pinpoint meatus is virtually never obstructed. Passing a feeding tube is typically unnecessary, as the child will eventually void given enough time.

Hematuria

Hematuria in the newborn often does not represent a significant process. One possible explanation is maternal hormonal withdrawal producing urethral bleeding through an as yet unspecified mechanism. Urine cultures, examination, and ultrasound evaluation are recommended. The appearance of hematuria may occasionally be noted in the diaper, produced by urate crystals that have a characteristic rusty red color. Other causes include RVT, which is identified on ultrasound examination.

Hypertension

Neonatal hypertension is rare and should prompt a careful evaluation of the infant's urinary tract by ultrasound with Doppler to identify the uncommon renal artery thrombosis. Iatrogenic renal injury from umbilical artery lines has been described to produce hypertension. Radioisotope renal scanning may be confirmatory by demonstrating focal or diffuse renal nonperfusion.

Urinary Ascites

The differential diagnosis of neonatal ascites includes urinary obstruction, which should be specifically sought, most efficiently with an ultrasound examination and a VCUG (Checkley et al, 2003). Posterior urethral valves are probably the most common underlying cause. Unusually, other obstructive processes may cause urinary ascites (Chun and Ferguson, 1997; Adams et al, 1998; Cimator et al, 2003; Beetz et al, 2004). Electrolyte analysis of the ascitic fluid may reveal high creatinine levels indicative of urine, but creatinine levels may also have equilibrated with the serum across the peritoneum.

Specific Diagnoses

Renal Vein Thrombosis

RVT in neonates is a rare condition of low mortality but high morbidity (Brandao et al, 2011). In the neonate, RVT is suggested by enlarged kidneys, hematuria, anemia, and thrombocytopenia, often with a history of a prolonged delivery and prematurity. Approximately 20% of infants with gross hematuria are found to have RVT, and about 20% of neonates with RVT have bilateral involvement. The presumed cause is impaired renal blood flow in the setting of a neonate with normally low blood pressure, polycythemia, and dehydration, including adrenal hyperplasia and salt wasting (Brandao et al, 2011). Conditions that may exacerbate those factors may predispose to RVT. Up to 50% of neonates with RVT are found to have prothrombotic abnormalities and should be screened (Kuhle et al, 2004; Marks et al, 2005). Thrombosis is peripheral and does not usually propagate centrally.

The diagnosis of RVT is best made using ultrasonography, in which an enlarged kidney is evident and the thrombus may be visualized directly (Brandao et al, 2011). Management of RVT is directed initially at reversing any predisposing factors such as dehydration and secondary electrolyte imbalances. Specific treatment remains controversial but may include anticoagulation with heparin or fibrinolytic therapy with streptokinase. Each of these modalities can be associated with significant complications (Nuss et al, 1994; Bokenkamp et al, 2000). When treated with heparin, fewer patients are left with renal functional abnormalities (Zigman et al, 2000). Bilateral RVT requires more aggressive therapy to prevent end-stage renal failure (Marks et al, 2005).

Adrenal Hemorrhage

Adrenal hemorrhage is a relatively common condition, estimated to occur in about 1% to 2% of healthy infants. More small adrenal hemorrhages are being detected with routine perinatal ultrasonography. Predisposing factors include prolonged labor, birth

trauma, and large birth weight. RVT may be associated (Suga et al, 2000). An association with BWS has been reported in several cases (Anoop and Anjay, 2004; Merrot et al, 2004; Gocmen et al, 2005). Clinically, the neonate with adrenal hemorrhage may have anemia, shock, and an abdominal mass. Gross hematuria is unusual. Ultrasonography is the most efficient diagnostic measure and usually reveals an echogenic suprarenal mass (Schwarzler et al, 1999; Velaphi and Perlman, 2001). This may appear similar to a neuroblastoma, and further evaluation, particularly with MRI, may be necessary. Scrotal hemorrhage may also be a presenting sign of adrenal hemorrhage (Avolio et al, 2002; Duman et al, 2004). The imaging characteristics of an adrenal hemorrhage evolve with time, often providing a definitive diagnosis as the mass is seen to involute. Calcifications may later develop. **The late appearance of an adrenal hemorrhage is that of peripheral eggshell calcifications in contrast to stippled calcifications of neuroblastoma.** Management is almost always supportive and expectant, with rare need for intervention.

Renal Artery Thrombosis

Hypertension and hematuria in a neonate should suggest the possibility of renal artery thrombosis (Roth et al, 2003). The clinical setting is usually suggestive in that umbilical artery catheterization is the most common cause of this condition. Renal insufficiency may be a clinical feature of this condition, as well as proteinuria and congestive heart failure (Andreoli, 2004; Cachat et al, 2004). Thrombotic involvement of the aorta may be present as well. Ultrasound examination usually reveals the diagnosis and the extent of the thrombus. Management is dependent on the clinical setting, and unilateral involvement is best managed expectantly, although thrombolytic therapy may be appropriate (Ellis et al, 1997; Kavalier and Hensle, 1997; Gunnarsson et al, 2000). Control of hypertension is the most important aspect of management and occasionally requires removal of a nonfunctional kidney.

SUMMARY

With the increased use of maternal-fetal ultrasound, more genitourinary abnormalities are being detected prenatally. Although advances in imaging have increased the detection and characterization of these abnormalities, further work is needed to identify which abnormalities are clinically significant. Research directives should focus on identifying which infants require postnatal diagnostic imaging and intervention. Developments in the fields of imaging, proteomics, and genomics may provide the necessary information to not only detect the abnormality but also prognosticate which abnormalities require further testing and medical intervention.

ACKNOWLEDGMENT

The authors acknowledge the assistance of Drs. Beryl R. Benacerraf, Bryann Bromley, Carol E. Barnewolt, Susan A. Connolly, and Judy A. Estroff for providing many of the fetal ultrasound images.

SECTION B Basic Principles

125 Urologic Evaluation of the Child

Thomas F. Kolon, MD, MS, and Douglas A. Canning, MD

Chief Complaint and History of Present Illness

Past Medical and Surgical History

Medications and Allergies in Pediatric Patients

Pediatric Urologic Examination

Pediatric Laboratory Evaluation

Pediatric Radiographic Evaluation

Pediatric Urodynamic Evaluation and Biofeedback Training

Office Surgical Procedures

Summary

Pediatric urology encompasses a spectrum of disorders ranging from complex congenital anomalies such as bladder or cloacal exstrophy to more routine but nevertheless important problems such as daytime wetting in a school-aged child. Thanks in part to the pioneers of past generations of pediatric urologists, most of these problems are easily diagnosed and treated. Despite the dramatic progress made over the past 50 years, new discoveries continue to contribute to improved care. These advances underscore the importance of continued investigation into the diagnosis and treatment of children with congenital or acquired pediatric urologic problems. This chapter focuses on the history and physical examination of the pediatric patient with a urologic problem. Particular emphasis is on clinical entities, examination techniques, and adjunct investigations that are unique to pediatric patients. The evaluation and treatment of a pediatric patient with a urologic problem are often complex. The reader may find further details about specific conditions in other chapters. This chapter presents an introduction to the nuances of the pediatric urologic evaluation.

CHIEF COMPLAINT AND HISTORY OF PRESENT ILLNESS

In most cases, the initial contact with the child and family is through a referring phone call from the parent, primary care physician, or, if prenatal evaluation is desired, the obstetrician. In many acute cases, the child's family is calling from a distance, and the urologist must decide with the referring clinician whether the child is healthy enough to be transferred or must first have his or her condition stabilized. Usually, even in remote areas, skilled general pediatric support is available. With coaching from the accepting team, most clinicians are able to manage complex problems in the stabilization phase of the triage process. A thorough understanding of the chief complaint, history of the present illness, and past medical history is essential to appropriate management of all pediatric patients with urologic problems.

"What can we do for your child?" usually begins the history in the pediatric patient with a urologic problem. In some cases, especially voiding dysfunction, the child can begin to answer

these questions, and it is worthwhile early in the interview to ask the child a few questions directly. This shows respect for the child, who may be an excellent historian despite young age. As soon as the child realizes that the interview is directed to him or her, rather than just to the parent, he or she will concentrate on the examination. If future therapy requires behavioral training that involves cooperation from the child, he or she may be more receptive. Additionally, it is often helpful to interview adolescents separately from their parents when asking sensitive questions, such as about sexual activity.

Abdominal Complaints

Children with acute abdominal pain should be seen immediately by a primary care physician or nonphysician provider and referred to urology if appropriate. An accurate history of the character of the pain may be the best indicator of the source of the pain. Details about the character of the pain, timing, acuity of onset, radiation, and migration are important and should be elicited directly from the child when possible. Associated loss of appetite, nausea, vomiting, or a change in bowel pattern may help to distinguish gastrointestinal from genitourinary sources. A thorough abdominal examination helps to rule out surgical abdominal disease. Causes of abdominal pain in children vary widely and are often unique to pediatric patients. Urologists usually suspect pyelonephritis, cystitis, or renal colic, but the differential diagnosis includes many nonurologic etiologies. Causes of intra-abdominal pain may include pyloric stenosis, midgut volvulus, appendicitis, intussusception, and constipation. Nonabdominal sources, such as sickle cell crisis or pneumonia, should also be considered. Occasionally, some children with spermatic cord torsion complain of abdominal pain and have few complaints referring to the scrotum. Usually an acute abdominal series is ordered, which shows considerable amounts of stool throughout the colon if constipation is the problem. Displacement of bowel away from an area of the abdomen is usually a harbinger for an abdominal mass. Most abdominal masses originate in genitourinary organs and should be evaluated immediately (Chandler and Gauderer, 2004) (Table 125-1). The most common malignant abdominal tumor in infants is

TABLE 125-1 Distribution of Abdominal Masses of 280 Patients in the Neonatal Period*

TYPE	NO.
KIDNEY (65%)	
Hydronephrosis (e.g., UPJ obstruction, UVJ obstruction, ureterocele)	80 (28%)
Multicystic kidney	63 (22%)
Polycystic kidney disease	18
Renal vein thrombosis	5
Solid tumor	13
Ectopy	4
TOTAL	183
RETROPERITONEUM (9%)	
Neuroblastoma	17
Teratoma	3
Hemangioma	1
Abscess	4
TOTAL	25
BLADDER (1%)	
Posterior urethral valves	2
FEMALE GENITAL SYSTEM (10%)	
Hydrocolpos	16
Ovarian cyst	13
TOTAL	29
GASTROINTESTINAL (12%)	
Duplication	17
Giant cystic meconium ileus	4
Mesenteric cyst	3
Ileal atresia	2
Volvulus (ileum)	2
Teratoma (stomach)	1
Leiomyosarcoma (colon)	1
Meconium peritonitis with ascites	1
Ascites	1
TOTAL	32
HEPATIC OR BILIARY (3%)	
Hemangioma (liver)	3
Solitary cyst (liver)	2
Hepatoma	1
Distended gallbladder	1
Choledochal cyst	1
Adenomatoid malformation of the lung	1
TOTAL	9

*Distended bladder, hepatomegaly, and splenomegaly were excluded in most series.

UPJ, ureteropelvic junction; UVJ, ureterovesical junction.

Data from [Griscom, 1965](#); [Emanuel and White, 1968](#); [Raffensperger and Abousleiman, 1968](#); [Wedge et al, 1971](#); and [Wilson, 1982](#).

neuroblastoma, followed by Wilms tumor ([Golden and Feusner, 2002](#)). Children with neuroblastoma typically relate a history of more constitutional symptoms than children with Wilms tumor. In newborns, the most common cause of an abdominal mass is hydronephrosis. If an abdominal mass is suspected, an abdominal ultrasound evaluation should be ordered. If the mass is solid, computed tomography (CT) or magnetic resonance imaging (MRI) is almost always required.

Scrotal Symptoms

A boy with acute scrotal pain must be presumed to have spermatic cord torsion regardless of age until proved otherwise. However, in some cases, an accurate history may save the boy an unnecessary surgical exploration. It is particularly important to interview the child as well as the parent. The differential diagnosis of acute scrotal pain includes testicular torsion, torsion of the appendix testis or appendix epididymis, epididymitis/orchitis, hernia/hydrocele, trauma, sexual abuse, tumor, idiopathic scrotal edema, dermatitis, cellulitis, and vasculitis such as Henoch-Schönlein purpura ([Gatti and Murphy, 2007](#)). Gradual onset of scrotal pain is more consistent with epididymitis, whereas abrupt pain suggests torsion of the spermatic cord or one of the appendices. Associated scrotal wall swelling, erythema, and superior displacement of the testis with an absent cremasteric reflex are very suggestive of spermatic cord torsion. However, the absence of edema or erythema or the presence of a cremasteric reflex does not rule out the possibility of acute testicular torsion, especially if the onset of pain was recent. The classic presentation of testicular torsion is the sudden onset of severe, unilateral pain that is often associated with nausea and emesis. A history of similar intermittent episodes may suggest intermittent testicular torsion. Traditionally, significant ischemic damage is believed to occur after 4 to 8 hours. **Testicular torsion represents a true surgical emergency**, and institutional transfers should be kept to a minimum, pending surgery and anesthesia availability. Patients presenting after 8 hours should still undergo surgical exploration because the viability of the testis is difficult to predict ([Beard et al, 1977](#); [Bartsch et al, 1980](#)).

Infants and children with an inguinal hernia or a hydrocele that changes in volume should be seen soon after diagnosis and more urgently if there is a history of inguinal or scrotal pain. Not all of these children need emergency surgery, but a few require surgical intervention within a short period. If there is a history of scrotal or inguinal pain, the child's parents should be taught to recognize the signs of an incarcerated inguinal hernia and instructed to go to the emergency department if symptoms occur before the planned surgical correction. **Infants with asymptomatic hydrocele rarely require surgery initially.** In most cases, the hydrocele resolves in the first year of life. We make an exception if the hydrocele is particularly large or palpable in the inguinal region. A large hydrocele with a palpable inguinal component or one that is enlarging may indicate the presence of an abdominoscrotal hydrocele. This type of hydrocele does not resolve spontaneously and usually enlarges tremendously. This hydrocele should be corrected usually at 6 to 12 months of age; an initial scrotal incision that decompresses the hydrocele makes the repair easier ([Luks et al, 1993](#); [Belman, 2001](#)).

Boys with undescended testes are among the most common referrals to the pediatric urologist. Undescended testes are present in 30% of preterm neonates and are present in 3% of full-term male infants at birth ([Ghirri et al, 2002](#); [Boisen et al, 2004](#)). Few undescended testes descend after 6 months of age. Although undescended testes do not represent a surgical emergency, **exploration for an undescended or absent testis should occur between 6 and 18 months of age** ([Berkowitz et al, 1993](#)). The only true emergency in cryptorchidism is a newborn phenotypic boy with bilateral nonpalpable testes because this patient may be a very masculinized girl with congenital adrenal hyperplasia (CAH). In prepubertal boys, concern for an undescended testis often reflects a retractile testis that results from a brisk cremasteric reflex and does not require surgical intervention. A retractile testis must be differentiated from an ascending testis, which may require an orchidopexy.

Varicocele is uncommon in a prepubertal boy but increases in incidence to around 15% by 15 years of age ([Schiff et al, 2005](#)). Varicoceles are primarily left-sided (90%) ([MacLellan and Diamond, 2006](#)). A right-sided varicocele in the absence of a left-sided varicocele should prompt an evaluation for a retroperitoneal process causing pressure on the right testicular vein. The initial gauge of testicular health is growth of the testes through puberty as measured by testis volume (via orchidometer or ultrasonography) ([Diamond et al, 2000](#)). Total testicular volume appears to correlate

more with future semen analysis than differential testicular volume; however, neither total nor differential testicular volume is a very good predictor of semen parameters (Christman et al, 2014). After puberty, semen analysis and hormonal levels should guide further treatment.

Prepubertal testicular and paratesticular tumors should be considered in the differential diagnosis of a scrotal mass. Although much less common than epididymal cysts or spermatoceles, a complaint of a painless testicular or paratesticular mass should be addressed immediately. A physical examination and scrotal ultrasonography should determine if the mass is concerning for neoplasia. In a contemporary series from a tertiary center, the most common prepubertal testis tumor was a teratoma followed by rhabdomyosarcoma, epidermoid cyst, yolk sac tumor, and germ cell tumor (Metcalf et al, 2003). This histologic distribution was corroborated by a multicenter review including four tertiary pediatric hospitals that demonstrated that 74% of prepubertal testicular tumors were benign, the most common being teratoma (48%). Yolk sac tumor accounted for only 15% of the tumors (Pohl et al, 2004). Although testicular tumors may arise in neonates as well as adolescents, the peak incidence of tumors in young children and infants occurs at age 2. In this specific population, yolk sac tumors are most common, and approximately 75% of tumors are malignant (Levy et al, 1994; Ciftci et al, 2001). Tumors of nontesticular origin such as leukemia and lymphoma must also be considered in pediatric patients.

Male Penile or Urethral Symptoms

Boys with painful priapism must be evaluated immediately. Pain may suggest ischemia of the corpus cavernosa, which can progress to corporeal fibrosis if untreated. Children with sickle cell anemia are especially at risk for priapism, with 75% of patients experiencing their first episode by age 20 years (Mantadakis et al, 1999; Adeyoyu et al, 2002). Outpatient treatment of this condition with penile corporeal aspiration and intracavernous injection of sympathomimetic drugs has been successful. Oral agents such as terbutaline or pseudoephedrine are not recommended in the management of acute ischemic priapism (>4 hours) (Montague et al, 2003).

Paraphimosis also requires immediate attention and manual reduction. In children, this procedure often requires a lidocaine penile block and some level of sedation. Conversely, phimosis is physiologic in young infants, and attempts to retract the foreskin manually in boys younger than 2 to 3 years old should be avoided. Phimosis in older children (potty trained) is typically treated with one or two courses of low-dose steroid cream and circumcision if medical treatment is unsuccessful (Ashfield et al, 2003).

Boys with hypospadias are seen routinely. Normally, we initiate the evaluation in the newborn period because most parents of a child with a congenital anomaly, even a relatively minor one such as hypospadias, desire an early opportunity to speak with a surgical specialist.

We evaluate children who have developed a complication after circumcision at the convenience of the family as long as there is no active bleeding, the child is voiding normally, and there is no injury to the penile shaft or shaft skin. Narrowing of the preputial ring after circumcision (cicatrix) may result in a trapped penis (Casale et al, 1999; Gillett et al, 2005). These infants usually can be managed with application of petroleum jelly to the penis for 4 to 6 weeks as healing continues. Alternatively, one or two courses of low-dose steroid cream as used for phimosis may also soften up the cicatrix enough to retract the ring and make the glans visible. As long as voiding remains normal during this period, the revision of the circumcision may be postponed until age 4 to 6 months when an outpatient surgical procedure can be performed. A more common complication, urethral meatal stenosis, may manifest at 6 months of age in circumcised infants (Upadhyay et al, 1998; Ahmed et al, 1999). This problem is also easily corrected in the office with a meatotomy under local anesthesia (Smith and Smith, 2000).

Female Genital Symptoms

Infant girls with introital masses commonly present to the pediatric urologist's outpatient office (Fig. 125-1). Vaginal masses may be palpable or may protrude from the introitus. The differential diagnosis of interlabial masses includes benign paraurethral cysts, hymen skin tags, urethral prolapse, imperforate hymen, prolapsed ureterocele, or, rarely, malignancies such as a vaginal rhabdomyosarcoma. Bladder outlet obstruction may result from a prolapsed ureterocele. Most of these lesions are differentiated by physical examination, but historical information such as pain, bleeding, or voiding difficulties helps solidify the diagnosis.

Urethral prolapse is relatively common, particularly in young African-American girls. Figure 125-1C shows urethral prolapse in a young girl. A urethral catheter demonstrates the circumferential prolapsed urethral tissue. The prolapse is through the meatus, forming a hemorrhagic, sensitive doughnut-shaped mass that bleeds with palpation or when in contact with the undergarments. Girls may have difficulty with urination depending on the size of the prolapse and whether it compromises the urethral meatus. Urethral prolapse often responds to topical application of estrogen and may be managed expectantly as long as voiding is normal (Redman, 1982). Rarely surgical excision is required.

Benign and malignant tumors of the vagina should be considered when vaginal bleeding occurs in young girls. A broad spectrum of entities including capillary hemangioma, rhabdomyosarcoma, and carcinoma may be associated with vaginal bleeding. Labial masses may be associated with hernia or hydrocele of the Nuck canal (Kizer et al, 1995). Labial adhesions (labia minora) are common and usually asymptomatic. Occasionally, a girl with labial adhesions complains of vaginal irritation from pooled urine. In this case, if the labial adhesions are not separated, the irritation may progress to irregular voiding that may exacerbate the problem of frequency and urgency. In some girls, a short course of estrogen cream applied to the labia may be effective; however, in many cases, separation of the adhesions, performed in the office after application of a local anesthetic cream, is required. Dense labial fusion may be associated with CAH, gonadal dysgenesis, or cloaca (Powell et al, 1995). A genitosinogram may be indicated in cases in which the urethra cannot be distinguished from the vaginal orifice and a urogenital sinus is suspected. Endoscopy of the common channel, urethra, and vagina and, in some cases, MRI have become more useful for surgical planning.

An adolescent girl who has not menstruated and in whom there is concern about a uterine or vaginal anomaly should be evaluated promptly. Many of these girls have an imperforate hymen or uterine anomaly that results in poor uterine drainage that may be uncomfortable. If such conditions are left untreated, retrograde drainage of the uterus may place the patients at risk of endometriosis and infertility (Rock et al, 1982). Patients with complete androgen insensitivity can also present with primary amenorrhea. Pelvic ultrasonography or MRI can delineate the anatomy further and guide intervention if necessary.

Sexual Abuse

Although genital injuries may be accidental, the possibility of physical or sexual abuse must be considered in all cases of genital trauma in girls or boys. Sexual abuse is common and includes any activity with a child before the age of legal consent that is for sexual gratification of an adult or a significantly older child. Sexual intercourse includes vaginal, oral, or rectal penetration, defined as entry into an orifice with or without tissue damage. Sex acts perpetrated by young children are learned behaviors and are usually associated with experiencing sexual abuse or exposure to adult sex or pornography. In 2011 in the United States, there were more than 850,000 reported cases of child maltreatment, including 61,472 cases of sexual abuse. More than half of these children were prepubertal at the time of the abuse. The perpetrator of the sexual abuse was most commonly a friend or neighbor, followed by a relative or day care worker (U.S. Department of Health and Human Services, 2012).

Figure 125-1. Female perineum examination. A, Normal. B, Labial adhesions. C, Urethral prolapse. D, Skene gland cyst (black arrow) with distorted urethral meatus (yellow arrow) and hymen (blue arrow). E, Imperforate hymen. F, Vaginal rhabdomyosarcoma.

The peak incidence of sexually transmitted infection is seen in the 10- to 14-year age group (Pandhi et al, 2003). In a study of women presenting to an urban sexual assault clinic, 43% were adolescents (Jones et al, 2003). Pelvic inflammatory disease rates are highest in females age 15 to 25 with 33% of infections in girls younger 19 years (Jenkins, 2000). Any pediatric patient with a sexually transmitted infection should be evaluated for sexual abuse. Although mode of transmission of human papillomavirus and herpes simplex virus is often unclear, *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infections in a prepubertal child should be reported to Child Protective Services (Bechtel, 2010).

The possibility of sexual abuse should be considered with associated physical symptoms, including vaginal, penile, or rectal pain, discharge, or bleeding or, less commonly, chronic dysuria, enuresis, constipation, or encopresis. In one study, 74% of pediatric patients with documented sexually transmitted infections had histories or signs of abuse (Pandhi et al, 2003). Sexual abuse should be considered when the vaginal mucosa is bruised or injected, the vaginal opening is dilated, or the hymen is damaged, showing a V-shaped notch or cleft (Walker, 1998). Despite these guidelines, the diagnosis of sexual abuse is often made by the history and not by the physical examination. In a review of 506 girls with a history of penetrative abuse referred to a sexual abuse clinic, only 11% had examination findings suggestive of sexual abuse (Anderst et al, 2009). Investigating the possibility of sexual abuse requires supportive, sensitive, and detailed history taking. Many hospitals have a sexual abuse team that can be consulted if sexual abuse is suspected. The key is to be aware of the possibilities when they might exist and to invite the team in early. A pediatric urologist is likely to be asked to evaluate the abdomen and perineum (Johnson, 2000). If abuse is suspected, it must be reported to the police. If the

perpetrator is a caregiver of the child or a parent, the state child welfare team must be contacted.

Voiding Symptoms

Voiding complaints and incontinence account for a large portion of any pediatric urology practice. Incontinence is classified as diurnal (daytime), nocturnal (nighttime), or both. If a child has never been dry, the incontinence is primary. If the child is wet after a dry interval greater than 6 months, the incontinence is secondary. **The ability to place children in categories based on the voiding history helps to focus the rest of the evaluation and guide further therapy.** The time and duration of the voiding disorder must be identified early in the interview. A thorough history obtained from the parents and the child is important to determine the actual pattern of voiding, which may differ from perceptions reported by the parent. Did symptoms begin before or after potty training? Is wetting associated with pain, urgency, or frequency? What is the character of the voiding? Is the urinary stream steady from beginning to end, or is it a stop-and-start (staccato) pattern suggestive of dysfunctional voiding? Are the symptoms worse at a particular time of the day? Does the child void frequently during the day but sleep through the night without wetting? Is wetting confined to the night, suggestive of primary nocturnal enuresis? Additionally, behavioral signs can be used to understand the etiology of functional incontinence further. Episodes of urgency in children are often suggested by holding maneuvers such as squatting, crossing legs (Vincent's curtsy), and sitting on the heel (Ellsworth and Caldamone, 2008). Poor potty habits may result in incomplete voiding or vaginal voiding. Giggle incontinence is encountered in young girls and refers to large volume incontinence that occurs only with laughter.

In this situation, the incontinence is associated with a complete emptying of the bladder and should be distinguished from stress urinary incontinence in adults because the treatment differs significantly (Berry et al, 2009).

The voiding history is incomplete without a record of the child's eating and drinking pattern. Does the child sip small amounts of water throughout the day rather than bolus drinking? Does the child drink large amounts of alternative liquids such as soft drinks, juices, or sports/energy drinks, which tend to be laden with salt and sugar and low in free water? What is the stooling pattern? Are bowel movements daily and soft, or are they firm, chunky, or pebblelike? Very few children are continent of urine and not stool. Conversely, children who retain stool nearly always retain urine. All of these are indicators of a dysfunctional emptying pattern, which may lead to urinary tract infection (UTI). Referencing a standardized stool chart, such as the Bristol stool form scale (Lewis and Heaton, 1997), may be helpful to clarify the stooling pattern further (Koh et al, 2010).

Children with daytime or nighttime wetting are evaluated routinely in the absence of other complicating problems. The care of children with nocturnal enuresis is individualized. Consideration of treatment should be reserved until after age 5. If the child does not perceive nighttime wetting as a problem, there is usually little advantage to treatment with medications or alarms. In our experience, only a few children younger than age 6 or 7 are bothered emotionally by nocturnal enuresis. Wetting during the day causes more concern and may indicate incomplete or infrequent voiding. Incomplete or infrequent voiding may lead to UTI, which may exacerbate wetting.

Although most voiding symptoms are secondary to voiding habits, more serious pathophysiology may manifest with similar complaints. After obtaining a careful history, any concerns regarding a structural etiology for voiding dysfunction should be investigated. Continuous leakage in between normal voiding patterns in a girl should raise concerns of an ectopic ureter. Symptoms suggestive of detrusor sphincter dyssynergia (e.g., difficulty emptying the bladder, urinary hesitancy, slow or weak urine stream, urinary urgency and/or frequency, dribbling urine after urination is complete) may represent occult spinal dysraphism. Urinary retention and stranguria may be caused by posterior urethral valves (PUV) or stricture in a boy or a bladder mass such as rhabdomyosarcoma in either a boy or a girl. Stranguria and retention should be red flags for the physician to delve deeper into the etiology of the symptoms. After a focused examination for epispadias, spinal dysraphism, or lower extremity weakness, a uroflow, postvoid residual, and ultrasound scan are usually appropriate first steps in the evaluation of voiding dysfunction and investigation of potential structural anomalies. Additional testing may include a voiding cystourethrogram (VCUG), retrograde urethrogram, spinal MRI or ultrasonography, and urodynamic evaluation.

Urinary Tract Infection

Febrile UTIs in newborns are treated emergently because newborns are particularly susceptible to significant renal damage if the infection is not treated promptly. These infants require intravenous antibiotics as early as possible after a urine culture has been obtained because they have a high prevalence of concomitant bacteremia (10% to 22%) (Pitetti and Choi, 2002). Appropriate antibiotic therapy administered without delay has been shown to reduce the incidence of scarring (Ransley and Risdon, 1981; Hiraoka et al, 2003). Some authors suggest this decreased incidence of scarring reflects a decreased likelihood of renal involvement rather than a true prevention of scar formation (Doganis et al, 2007).

Febrile UTIs in children older than newborns should also be treated promptly. Children of all ages with a severe UTI may be subject to renal scarring (Ransley and Risdon, 1981; van der Voort et al, 1997) and should be seen within 24 hours or sooner. **Children older than newborns with afebrile UTI should be seen semiurgently.** In practice, many of these patients are seen by their pediatrician and are seen in follow-up by a pediatric

urologist. Nearly all children with culture-proven UTI should be evaluated initially with ultrasonography, whereas the role of further evaluation with VCUG or renal nuclear scans continues to be investigated.

The evaluation for UTI is completed at the parent's convenience after the initial infection has been treated. In most cases, radiologic studies after a UTI in a child include a renal and bladder ultrasound scan looking for hydronephrosis or bladder changes that may be associated with obstruction and a VCUG to detect vesicoureteral reflux (VUR). However, a substantial number of cortical defects on technetium-99m (^{99m}Tc) dimercaptosuccinic acid (DMSA) scan occur in the absence of identifiable reflux (62% to 82%) (Majd and Rushton, 1992; Benador et al, 1997; Ditchfield and Nadel, 1998; Biggi et al, 2001; Ditchfield et al, 2002). This finding led to a re-evaluation of the role of VCUG as the initial investigation in a child with a UTI. **Infants younger than 6 months old and uncircumcised male infants are at increased risk for recurrent UTI** (Shim et al, 2009).

At the present time, the appropriate workup for a febrile UTI is in a state of flux. The American Academy of Pediatrics clinical practice guideline aims to enhance the clinical diagnosis of UTI in children 2 months to 2 years old (American Academy of Pediatrics, 2011). It attempts to rationalize the use of antibiotics for pediatric UTI and does not recommend a VCUG for a first-time febrile UTI with a normal ultrasound scan. However, the guideline based conclusions on limited and flawed data that have a very narrow scope of applicability. Very close follow-up of patients treated based on the American Academy of Pediatrics clinical practice guideline protocol is required to assess patient and physician adherence to the guideline and assess further the clinical impact in terms of population incidence of acute pyelonephritis and renal damage.

Hematuria

A practical approach to the evaluation of hematuria in children is presented in Chapter 123. Isolated microhematuria is very common and usually self-limited without a sign of an underlying disease (Vehaskari et al, 1979; Hogg, 2009). Most children with microscopic hematuria are evaluated and the source of the hematuria is never identified (Diven and Travis, 2000). The most commonly identified etiology of asymptomatic microhematuria and gross hematuria in children is hypercalciuria (Bergstein et al, 2005; Parekh et al, 2002). Microscopic hematuria in the absence of other symptoms is not an emergency in children.

Gross hematuria in children is less common than microscopic hematuria, with an estimated prevalence of 1.3 per 1000 (Ingelfinger et al, 1977). The most common diagnoses are UTI (26%), perineal irritation (11%), trauma (7%), meatal stenosis with ulceration (7%), coagulation abnormalities (3%), and urinary tract stones (2%). The most common glomerular causes of gross hematuria in children are poststreptococcal glomerulonephritis and IgA nephropathy. An antecedent sore throat, pyoderma, edema, or red blood cell casts suggest glomerulonephritis. IgA nephropathy can cause recurrent gross hematuria with flank or abdominal pain and may be preceded by an upper respiratory tract infection (Meyers, 2004). Adenovirus infection, hypercalciuria, and hyperuricosuria are other sources to consider. A renal and bladder ultrasound scan is usually performed for gross hematuria, although the yield is low (Fernbach, 1992). In contrast to adult patients, cystoscopic examination in children rarely reveals a cause for hematuria, but it should be performed when bladder pathology is a consideration.

Gross hematuria in a newborn is an emergency because it may indicate renal vein thrombosis or renal artery thrombosis. Both conditions may be life-threatening. Renal vein thrombosis has an incidence of 2 to 5 per 100,000 births, affects boys twice as often as girls, and has a left-sided predominance. The historical clinical triad includes hematuria (50%), abdominal mass (41%), and thrombocytopenia (29%) with 13% of patients presenting with all three findings. Preexisting clinical conditions associated with renal vein thrombosis include dehydration, sepsis, birth

asphyxia, congenital vein defects, polycythemia, maternal diabetes, traumatic delivery, indwelling umbilical venous catheter, and prematurity. Affected infants require resuscitation with intravenous fluids and, occasionally, anticoagulant or antithrombotic therapy (Kuhle et al, 2004; Chang et al, 2007). Renal artery thrombosis occurs primarily after umbilical artery or femoral artery catheterization; in infants of diabetic mothers; and in some cases of severe dehydration, hemoconcentration, coagulopathy, or vasculitis. The initial treatment involves withdrawal of the catheter and hydration. Both entities can be diagnosed with renal Doppler ultrasonography (Martin et al, 1988). **Gross hematuria after the newborn period, although not life-threatening, should be evaluated without delay.** Many children have an easy-to-recognize source such as UTI, urethral prolapse, trauma, and meatal stenosis with ulceration, coagulation abnormalities, or urinary tract stones. Less obvious sources include acute nephritis, ureteropelvic junction (UPJ) obstruction, cystitis cystica, epididymitis, or tumor (Diven and Travis, 2000; Meyers, 2004). Similar to adult patients, a thorough history including a specific description of the color of the urine, the presence of clots, and timing of hematuria such as terminal hematuria or hematuria on initiation of voiding should facilitate the diagnostic process. A directed history should include medications, exercise habits, propensity for bleeding diathesis, and a travel history to rule out exposure to infectious diseases such as schistosomiasis or tuberculosis.

Renal Trauma

A pediatric patient with trauma usually presents to the emergency department and is evaluated by the emergency medicine and trauma teams often with the assistance of the urology service. Blunt force trauma is the primary mechanism for major renal trauma (Mohamed et al, 2010). The kidney in children is particularly susceptible to trauma because of the limited visceral adipose tissue, limited chest wall protection, relatively increased renal size, and increased mobility of the kidney (Brown et al, 1998). A thorough history including mechanism of injury should be obtained from the patient or observers. **Epidemiologic data demonstrate that most renal injuries result from motor vehicle accidents; falls; or high-velocity activities such as sledding, skiing, all-terrain vehicle accidents, and skateboarding** (Margenthaler et al, 2002; Rogers et al, 2004). Injuries resulting from these types of accidents should alert the clinician to potential renal damage. The history should include any congenital renal anomalies, such as a UPJ obstruction, a solitary kidney, or renal ectopia. Finally, associated injuries must be evaluated. Any case of an abdominal injury in a toddler or young child without an antecedent history of blunt force trauma should be evaluated for physical abuse (Barnes et al, 2005).

Blunt force renal trauma represents a urologic emergency that requires immediate attention but does not usually require operative intervention. Conservative treatment of high-grade blunt renal injuries has been successfully described in children. Blunt trauma accounts for 89% of pediatric renal trauma with a renal exploration rate of less than 2%. Of grade IV renal injuries, 41% were successfully managed nonoperatively based on CT scan staging in hemodynamically stable children with an overall renal salvage rate greater than 99% (Buckley and McAninch, 2004). A consecutive series of 101 patients with blunt renal injury from The Children's Hospital of Philadelphia demonstrated that a nonoperative management strategy was advantageous and successful in 95% of pediatric blunt renal injuries (Nance et al, 2004). Penetrating trauma represents the remaining 11% of renal injuries with a renal exploration rate of 76%.

Children with high-grade injuries such as major vascular avulsion or extensive urinary extravasation, especially in the setting of UPJ disruptions, are at risk for failure of conservative management (Henderson et al, 2007). These patients warrant close urologic observation and repeated examinations. We recommend conservative management, recognizing that a complete evaluation is necessary to determine accurately which patients require further intervention.

Ambiguous Genitalia

Infants with ambiguous genitalia require immediate evaluation. Many infants require direct transfer from a referring hospital. **Because CAH may result in salt wasting, which may be life-threatening, infants with ambiguous genitalia must be evaluated quickly and stabilized (Forest, 2004).** If CAH is suspected, the infant should not be discharged home from the nursery before appropriate testing is complete. In some cases, a genotypic female neonate with CAH may be incorrectly identified as a male neonate. The correct diagnosis should be made as quickly as possible to establish the appropriate sex of rearing. Infants with ambiguous genitalia may also have other syndromes and may require further evaluation (Tables 125-2 and 125-3 on the Expert Consult website). A history of a discordant karyotype from an amniocentesis and infant phenotype should prompt an evaluation. The parents should be asked about a family history of infertility, amenorrhea, and infant mortality. Complete evaluation of infants with ambiguous genitalia should include evaluations from urology, endocrinology, genetics, and psychology. For differential diagnosis and treatment purposes, the most important physical finding is the presence of one or two gonads. If no gonads are palpable, all disorder of sex development (DSD) categories are possible. Of these, 46,XX DSD is most commonly seen followed by 45,X/46,XY. A palpable gonad is highly suggestive of a testis or, rarely, an ovotestis because ovaries and streak gonads do not descend. If one gonad is palpable, 46,XX DSD is less likely, whereas 45,X/46,XY, ovotesticular DSD, and 46,XY remain possibilities. If two gonads are palpable, 46,XY and rarely ovotesticular DSD are the most likely diagnoses.

In the immediate newborn period, all patients require a karyotype and laboratory evaluation by serum electrolytes, 17-hydroxycorticosteroid (17-OH) progesterone, testosterone, luteinizing hormone, follicle-stimulating hormone, and urinalysis. Chromosomal studies from an amniocentesis do not negate the need for a postnatal karyotype. When the karyotype is determined, serum analysis assists in narrowing the differential diagnosis. If the 17-OH progesterone level is elevated, a diagnosis of CAH can be made. Determining 11-deoxycortisol and deoxycorticosterone levels can help differentiate between 21-hydroxylase and 11 β -hydroxylase deficiencies. If the levels are elevated, a diagnosis of 11 β -hydroxylase deficiency can be made, whereas low levels confirm 21-hydroxylase deficiency. If the 17-OH progesterone level is normal, a testosterone/dehydrotestosterone ratio along with androgen precursors before and after human chorionic gonadotropin (hCG) stimulation helps elucidate the 46,XY DSD etiology. A testosterone/dehydrotestosterone ratio of greater than 20 is suggestive of 5 α -reductase deficiency. Serum levels of antimüllerian hormone (or müllerian-inhibiting substance) and inhibin B can also be measured in the immediate postnatal period to document the existence of normal testicular tissue. An immeasurable antimüllerian hormone level or a failure to respond to hCG in combination with elevated luteinizing hormone and follicle-stimulating hormone levels is consistent with anorchia. For the first 60 to 90 days of life, a normal gonadotropic surge occurs with a resultant increase in the testosterone level and its precursors. During this specific time period, hCG stimulation for androgen evaluation can be postponed. Examination of the internal genitalia can be achieved using many modalities, including abdominal and pelvic ultrasonography, MRI, fluoroscopy, endoscopy, and laparoscopy. An ultrasound scan should be the first radiologic examination performed because it is noninvasive, quick, and inexpensive.

Antenatal Hydronephrosis

In neonates with antenatally detected hydronephrosis and a normal bladder, the postnatal evaluation of the hydronephrosis begins within the first few days of life. Families are usually concerned about the diagnosis and anxious to establish a management plan. The postnatal evaluation can be scheduled at the family's convenience for most infants. This classification includes infants with a history of prenatal hydronephrosis who are not suspected to have bladder

TABLE 125-2 Syndromes Associated with Multisystemic Disease

SYNDROME	INHERITANCE	RENAL ANOMALIES	GENITAL ANOMALIES	ANOMALIES IN OTHER SYSTEMS
Aarskog-Scott			Shawl scrotum, cryptorchidism	Broad facies, short stature
Beckwith-Wiedemann		Wilms tumor		Macroglossia, gigantism, hepatoblastoma
Carpenter	AR		Small genitalia	Acrocephaly, polydactyly
Caudal regression		Hydronephrosis, renal agenesis	Vaginal and uterine agenesis	Imperforate anus, LS spine abnormality
Cerebro-oculofacial	AR	Renal agenesis	Cryptorchidism	Arthrogryposis, microcephaly, cataracts
CHARGE			Small genitalia	Coloboma, heart defects, ear anomalies
Cornelia de Lange			Small genitalia, cryptorchidism	Micromelia, bushy eyebrows
Curran		Renal agenesis		Acral anomalies
Donohue			Enlarged penis or clitoris	Hirsutism, elfin face, thick lips, low-set ears
Drash		Wilms tumor, glomerulonephritis	Mixed gonadal dysgenesis	
Dubowitz	AR		Hypospadias, cryptorchidism	Eczema, small stature, peculiar facies
Ehlers-Danlos	AR	Hydroureter		Skin hyperextensibility, poor wound healing
Fraser			Hypospadias, cryptorchidism	Cryptophthalmos
G			Hypospadias	Esophageal defect, low-set ears, abnormal facies
Holt-Oram		Renal anomalies		Defects of upper limb
Laurence-Moon-Biedl			Small genitalia	Obesity, retinal pigmentation, polydactyly
Marfan	AD	Renal duplication, hydroureter	Cryptorchidism	Aortic aneurysm, arachnodactyly
Mayer-Rokitansky		Renal agenesis	Duplex uterus, vaginal atresia	
Meckel-Gruber	AR	Renal cysts	Ambiguous genitalia, cryptorchidism	Microcephaly, polydactyly
Menkes		Hydronephrosis, reflux	Cryptorchidism	Kinky hair, CNS abnormality
Ochoa		Neurogenic bladder, hydronephrosis	Cryptorchidism	Aortic aneurysm, arachnodactyly
Opitz	AR		Hypospadias, cryptorchidism	Hypertelorism, mental retardation
Prader-Willi			Cryptorchidism	Hypotonia, obesity, mental retardation
Prune-belly		Hydronephrosis	Cryptorchidism	Hypoplastic abdominal muscle
Robert	AR	Hydroureter	Hypospadias, large penis, cryptorchidism	Hypomelia, growth retardation
Robinow	AD		Small genitalia, cryptorchidism	Flat face, short forearms
Rubinstein-Taybi	AR		Chordee	Hypoplastic maxilla, broad thumbs and toes
Rudiger	AR	Hydroureter	Small penis	Bicornuate uterus, coarse facies, stub nose
Russell-Silver	AR	Nonspecific renal anomalies	Small penis, hypospadias, cryptorchidism	Short stature, café au lait spots, skeletal asymmetry
Seckel	AR		Small genitalia, cryptorchidism	Small head, beak nose

outlet obstruction based on the postnatal ultrasound scan. Additionally, the ultrasound scan must not demonstrate bilateral severe hydronephrosis, a solitary kidney, or a thickened bladder wall, and the infant should be thriving.

The postnatal history should also include the sex of the infant, laterality of the hydronephrosis, the level of obstruction (i.e., UPJ, ureterovesical junction, urethra), gestational age of onset, history of oligohydramnios, and any other associated anomalies. Access to prenatal records and fetal ultrasound scans is extremely useful. Additional tests to be scheduled include a repeat ultrasound scan and possibly a VCUG (for VUR or PUV) or a ^{99m}Tc mercaptoacetyltriglycine (MAG3) diuretic renal scan (for renal function and drainage). Most neonates are maintained on amoxicillin prophylaxis until this postnatal evaluation is completed. The differential diagnosis for antenatal hydronephrosis most commonly includes UPJ obstruction, VUR, ectopic ureter, ureterocele, megaureter (ureterovesical junction obstruction), multicystic dysplastic kidney, PUV, prune-belly syndrome (PBS), and megacystis-microcolon syndrome.

Certain conditions require more immediate intervention, especially when bladder outlet obstruction is present. If PUV are considered, the bladder should be drained with a feeding tube, and a VCUG should be performed at an appropriate interval. Conversely, if PBS is considered, urethral catheterization should be avoided if possible to minimize the risk of UTI. Additionally, a ureterocele may obstruct the bladder outlet and result in bilateral upper tract dilation. This situation can be ameliorated by placement of a urinary catheter.

An increasing number of pregnant women carrying a fetus with hydronephrosis seek prenatal evaluation with the urologist. These visits are scheduled within a week from the time of referral unless the following conditions exist: (1) There is bilateral hydronephrosis or hydronephrosis in a single system kidney, (2) there is oligohydramnios, and (3) there is evidence of significant cystic renal disease in a fetus less than 22 weeks' gestational age. In these cases, a more rapid consultation is preferred. After discussion with an obstetrician specializing in high-risk pregnancy, fetal intervention may be indicated in some cases of oligohydramnios, bladder outlet obstruction, and retained adequate renal function.

Congenital Anomalies in Neonates

Patients with major abdominal defects such as classic bladder or cloacal exstrophy require direct admission to the neonatal intensive care unit for stabilization and surgical planning. In many cases, a team is assembled and provides orthopedic, general surgical, and urologic care during the surgery (Jeffs, 1978; Lattimer et al, 1979; Gearhart, 1999). Patients with imperforate anus and variants such as a cloacal anomaly require initial decompression of the intestinal tract, usually within the first 24 to 48 hours (Chen, 1999). At the time of the colostomy, the urologist may evaluate the perineum and perform endoscopy to assess the urinary anomalies further. Procedures to correct these major defects must be planned by surgeons who are familiar with the potential risks and complications associated with the reconstruction of the urethra, vagina, and colon. The anesthesia team and neonatologists must be skilled in the management of the complex metabolic changes that may occur in infants who are under anesthesia for long periods and have critical postoperative care.

Spina bifida is the most common birth defect of the central nervous system, affecting about 1500 infants born each year in the United States. For many newborns with spinal dysraphisms, the diagnosis is made in utero, and fetal repair may be offered (Adzick et al, 2011). Evaluation and follow-up of newborns with a fetal repair are similar to the evaluation and follow-up of neonates who did not undergo fetal repair. Most of these infants do not experience urinary retention initially, but many develop spinal shock after neurosurgery in the newborn period and have a transient period of overflow urinary drainage. As soon as possible after closure of the spinal defect, a baseline renal and bladder

ultrasound scan is performed to evaluate for evidence of bladder or upper tract abnormalities. An initial urodynamic investigation is performed after resolution of the spinal shock to ensure that bladder storage pressures are not excessive (Bauer, 1998; Adzick et al, 2011). High-risk infants (infants with a detrusor leak point pressure >40 cm H₂O or detrusor-sphincter dyssynergia) are started on anticholinergic therapy and intermittent catheterization (Snodgrass and Adams, 2004). Infants with normal urodynamic findings require close follow-up because of the risk for subsequent neurologic deterioration secondary to spinal cord tethering (Tarcen et al, 2001).

KEY POINTS: CHIEF COMPLAINT AND HISTORY OF PRESENT ILLNESS

- Pediatric diagnoses should be triaged into the following categories: emergent, urgent, semiurgent, and routine.
- Acute scrotal pain must be evaluated emergently because of the risk of spermatic cord torsion, regardless of age.
- Neonates with bilateral hydronephroses or hydronephrosis in a solitary kidney should be evaluated immediately after birth in the newborn nursery.
- If CAH is suspected, the evaluation should be completed before hospital discharge.
- If sexual abuse is suspected, the sexual abuse team should be immediately consulted, and appropriate interventions should be initiated.

PAST MEDICAL AND SURGICAL HISTORY

A past medical and surgical history is always germane to the patient's current history and often provides insight into the current condition. Many pediatric congenital syndromes include urologic anomalies (see Tables 125-2 and 125-3 on the Expert Consult website), and the pediatric urologist should be aware of these associations. Additionally, an assessment of the child's developmental progress may be relevant to their urologic development, especially in the context of potty training and enuresis. A summary of developmental milestones is provided in Table 125-4.

Other pediatric conditions affect the timing of surgical intervention and affect the level of risk from anesthesia. In healthy children, a recent history of a respiratory illness or reactive airways disease increases the risk of general anesthesia (Schreiner et al, 1996; Parnis et al, 2001). Preterm infants are also at increased risk of anesthetic complications and postoperative apnea. As a result, many of these infants require postoperative cardiopulmonary monitoring. Neonates with a history of apnea are at highest risk (Murphy et al, 2008). Other infants have severe cardiac anomalies and may benefit from a pediatric anesthesiologist with cardiac experience. Although the pediatric anesthesiology team assesses the child for anesthetic risk, the pediatric urologist should be aware of these conditions as well. Finally, all bleeding dyscrasias, such as von Willebrand disease, should be evaluated by a pediatric hematologist before surgery.

MEDICATIONS AND ALLERGIES IN PEDIATRIC PATIENTS

Medications are typically dosed based on weight (e.g., milligrams per kilogram). An accurate weight must be obtained in pediatric patients before prescribing most medications. Additionally, many adult medications are contraindicated in children, and pediatric guidelines should be consulted. For example, aspirin has been associated with Reye syndrome in children and adolescents and is not recommended for the treatment of fever in children. Acetaminophen (10 to 15 mg/kg every 4 hours) or ibuprofen (5 to 10 mg/kg every 6 hours) is not associated with significant

TABLE 125-4 Developmental Milestones

AGE (mo)	GROSS MOTOR	FINE MOTOR	SOCIAL SKILLS	LANGUAGE
3	Supports weight on forearms	Opens hands spontaneously	Smiles appropriately	Coos, laughs
6	Sits momentarily	Transfers objects	Shows likes and dislikes	Babbles
9	Pulls to stand	Pincer grasp	Plays pat-a-cake, peek-a-boo	Imitates sounds
12	Walks with one hand held	Releases an object on command	Comes when called	1-2 meaningful words
18	Walks upstairs with assistance	Feeds from a spoon	Mimics actions of others	At least 6 words
24	Runs	Builds a tower of 6 blocks	Plays with others	2- to 3-word sentences

From Haslam RHA. Neurological examination. In: Behrman R, Kliegman R, Jenson H, editors. Nelson textbook of pediatrics. 16th ed. Philadelphia: Saunders; 2000.

adverse effects. However, overdoses of acetaminophen can lead to hepatic failure. Trimethoprim-sulfamethoxazole is contraindicated in preterm infants and full-term infants younger than 2 to 3 months old because of the risk of kernicterus. Sulfonamide medications can be initiated after 2 to 3 months of age (Fefer and Ellsworth, 2006).

Allergies should be recorded for all patients and be clearly documented. Among pediatric patients with urologic problems, children with myelomeningocele and children with an increased number of operations and/or surgery in the neonatal period are at increased risk for latex allergies, and latex precautions should be instituted in these patients (Pires et al, 2002).

KEY POINTS: PAST MEDICAL AND SURGICAL HISTORY AND MEDICATIONS AND ALLERGIES IN PEDIATRIC PATIENTS

- Congenital urologic anomalies are often associated with known syndromes, and the pediatric urologist should be aware of concurrent conditions.
- Pediatric pulmonary conditions have a direct impact on the anesthesia risk and should be evaluated before surgical intervention.
- Aspirin is associated with Reye syndrome and should be avoided in children.
- Patients with myelomeningoceles are at greater risk for latex sensitivity, and latex precautions should be used.

PEDIATRIC UROLOGIC EXAMINATION

General Examination

In most cases, the primary care physician has identified a problem that requires review by a pediatric urologist. However, because other processes may coexist, the urologist must be alert for evidence of disease in other organ systems. Although few children are severely ill when evaluated in the urologist's office, it is important to develop the skills to recognize an infant or child who requires hospitalization. The ability to determine when an infant requires an inpatient admission is particularly important because the metabolic reserve is less abundant in a newborn (Park, 2000). When attempting to determine the severity of illness, particularly in an infant or small child, observation of the child and a careful history from the parent may be more important than the vital signs or the physical examination. The child's color (pale or cyanotic), level of alertness, response to the parent's comforting, and quality of interaction with the examiner and the quantity of tearing while crying may provide considerable information about mental status and level of hydration. If the child's response in any of these areas suggests severe illness, the child should be transferred to the

emergency department, where appropriate resuscitation can be delivered while the diagnostic evaluation continues. In the acute emergency department setting, a full general and urologic examination must be performed by the evaluating medical team. Patients with hemodynamic instability must be emergently addressed.

In the office, vital signs should be recorded for every new patient, and for children with a history of renal anomalies or VUR, vital signs should be recorded on all subsequent visits. Because **blood pressure and heart rate change as a function of age**, reference ranges for blood pressure and pulse rates for boys and girls should be posted in the clinic near where the vital signs are taken (Bernstein, 2000). Assistants taking the blood pressure should be aware of the variation with age and should notify the team of blood pressure readings greater than the 90th percentile. On entering the room, a clinician can address both the child and the parent to encourage the child to participate in the examination process. Physical examination in young children can be challenging, and the clinician must attempt to create a favorable environment. Examining a child on his or her mother's lap can be useful in comforting a frightened child. Additionally, sitting or kneeling near a young child facilitates interaction at the child's level.

Abdominal and Flank Examination

When examining the abdomen, the examiner's other hand should be placed behind the flank to help palpate the kidney on either side. If the abdomen is supple, the approximate size and location of each kidney may be determined with deep palpation. An attempt should be made to feel the liver edge, spleen, and colon, particularly the descending colon. In the newborn, the liver may be palpable, sometimes 2 cm below the ribs on the left. When examining the left lower quadrant, an estimate should be made of the volume of stool in the descending colon. In infants, a large amount of gas may be present within the gastrointestinal tract. The abdominal wall is normally weak, especially in premature infants. An abdominal examination can be performed on a crying infant during inspiration when the anterior abdominal muscles are relaxed. Separation of the rectus muscles and umbilical hernias are common in newborns. The abdominal wall is lax and protuberant in boys with PBS. Occasionally, children with other types of bladder outlet obstruction or profound antenatal hydronephrosis also have considerable laxity of the abdominal muscles. The abdomen should be inspected for other abnormalities, such as ventral hernia, flaring of the rib cage, umbilical leakage, mass, or hernia. Unusual masses should be investigated immediately with ultrasonography.

Renal pathology is the cause of two thirds of neonatal abdominal masses (Pinto and Guignard, 1995). Cystic abdominal masses include hydronephrosis; multicystic dysplastic kidney; adrenal hemorrhage; hydrometrocolpos; intestinal duplication; and choledochal, ovarian, omental, or pancreatic cysts. Solid masses include neuroblastoma, congenital mesoblastic nephroma, hepatoblastoma, and teratoma. A solid flank mass may be due to renal venous thrombosis, which becomes apparent with signs of hematuria, hypertension, and thrombocytopenia. In neonates,

transillumination of the abdomen may assist in distinguishing between solid and cystic lesions.

Abdominal distention at birth or shortly afterward suggests either obstruction or perforation of the gastrointestinal tract often secondary to meconium ileus. Later distention suggests bowel obstruction, sepsis, or peritonitis. Abdominal wall defects may be present through the umbilicus (omphalocele) or lateral wall (gastroschisis). Omphaloceles are associated with other anomalies and syndromes, such as Beckwith-Wiedemann syndrome, conjoined twins, trisomy 18, meningomyelocele, and imperforate anus (Hassink et al, 1996; Chen et al, 1997; Kallen et al, 2000). In bladder exstrophy, the posterior bladder wall is visible through a midline defect in the abdominal wall, and a pubic diastasis is appreciated. In addition, a bifid clitoris or epispadias is present. In cloacal exstrophy, an omphalocele is superior to the cecal plate and lateral bladder halves with prolapsed ileum typically in the midline. A bifid clitoris or penis, imperforate anus, and spinal abnormalities also are present.

Many patients presenting with blunt force renal trauma have associated extrarenal injuries such as other solid organ injuries, a pneumothorax, pelvic fractures, and bladder or urethral injuries, and a complete physical examination is essential (Margenthaler et al, 2002; Mohamed et al, 2010). During an examination for renal trauma, the urine should be assessed for gross hematuria. Insertion of a urethral catheter should be postponed in the setting of gross hematuria until the lower urinary tract is assessed by the urology team.

Genital Examination

Scrotal Examination

The patient should be examined in a warm room supine in the frog-leg position with both legs free. To begin the scrotal examination, the inguinal canal should be inspected on each side for signs of asymmetry or mass. The examiner's nondominant hand closes the internal inguinal ring (Fig. 125-2). This maneuver prevents an intracanalicular testis from migrating into the abdomen. The inguinal canal is palpated to identify a fullness or mass suggestive of a hernia or hydrocele of the spermatic cord. The examiner may feel a "silk glove" sign (sensation of rubbing two pieces of silk together when gently palpating the cord at the pubic tubercle with a single finger) suggestive of a thickened patent processus vaginalis that may be present if a hernia is intermittent. The examiner's dominant hand is brought down to the scrotal area, and the testis is palpated. It is important to determine size, location, and texture of both gonads, with consideration of the anatomy of the testis, the epididymis, and the vas deferens, if palpable. The undescended testis

may be found in the inguinal canal; in the superficial inguinal pouch; at the upper scrotum; or, rarely, in the femoral, perineal, or contralateral scrotal regions. In an infant with a possible DSD, a symmetrical gonadal examination (gonads palpable on each side or impalpable on both sides) suggests a global disorder such as CAH or androgen insensitivity. Asymmetry in the gonadal examination suggests a localized problem, such as mixed gonadal dysgenesis or ovotesticular DSD.

The examiner should note the development and pigmentation of the labioscrotal folds along with any other congenital anomalies of other body systems. Abnormal phallic size, the position of the urethral meatus, and the amount of penile curvature should be described, and the number of perineal orifices should be noted. Another critical finding on physical examination is the presence of a uterus that can be palpated by digital rectal examination as an anterior midline cordlike structure. A thorough general physical examination must be performed as well. Blood pressure should be measured to rule out hypertension. The presence of hyperpigmentation should also be documented. Dysmorphic features indicating syndromic manifestations (e.g., short broad neck, widely spaced nipples, or aniridia) should be noted.

The acutely painful scrotum should be examined carefully to determine the true etiology. Testicular torsion may manifest with varied clinical findings, but the involved testis often demonstrates signs such as higher riding in the hemiscrotum, a transverse orientation, an anterior epididymis, absent cremasteric reflex, and tenderness of the testis and epididymis. In contrast, torsion of the appendix testis or appendix epididymis often results in localized tenderness at the superior pole of the testis or caput epididymis and is often associated with a reactive hydrocele. Additionally, in boys with thin scrotal skin, the "blue dot" sign can be seen reflective of a necrotic appendix. Epididymitis classically has a gradual onset and is not associated with nausea or emesis (Gatti and Murphy, 2007).

The normal newborn scrotum is relatively large. Its size may be increased with the trauma of breech delivery or by a newborn hydrocele, which can be distinguished from hernia by palpation and transillumination as well as by the absence of a mass in the inguinal canal. In the absence of volume changes within the hydrocele, the processus vaginalis is usually not patent, and the newborn hydrocele resolves by 1 year of age without surgery. Persistence of a hydrocele beyond 12 to 18 months even in the absence of volume changes usually indicates a patent processus vaginalis and is an indication for surgical ligation of the processus vaginalis and incision of the scrotal component of the hydrocele. Neonatal extravaginal testicular torsion can also occur prenatally resulting in a firm, enlarged, nontender mass in the hemiscrotum that is usually associated with dark discoloration of the overlying skin. A normal scrotal examination at birth and subsequent development of erythematous, tender, edematous hemiscrotum suggests postnatal extravaginal testicular torsion and should be addressed immediately with surgical intervention if the neonate is clinically stable.

Retractile testes in some cases may be difficult to distinguish from a low undescended testicle. Placing the child in a squatting (catcher's position) or legs-crossed position sometimes relaxes the reflex and facilitates palpation of the testis. A testis is descended if it can be manipulated to the base of the scrotum and remains there after release without tension. Testes that feel tethered during manipulation and cannot be manipulated to the base of the scrotum are at risk for becoming ascending testes. If doubt exists, a second examination 6 to 18 months later may be helpful to distinguish a retractile testis from a tethered testis. As the child ages, an ascending or tethered testis (both cryptorchid testes) becomes more and more difficult to manipulate into the bottom of the scrotum (Eardley et al, 1994; Clarnette and Hutson, 1997; Davey, 1997).

Scrotal masses can be transilluminated to determine if the component is primarily fluid, such as a tense hydrocele, or solid, such as a testicular tumor. If a firm intratesticular mass is palpated, a thorough examination of the lymph nodes should be performed to evaluate for lymphoma, leukemia, or metastatic disease. Patients with a nontender testicular mass and signs of precocious puberty should be evaluated for a Leydig cell tumor or less commonly a

Figure 125-2. Clinical examination of the male groin.

Sertoli cell tumor (Agarwal and Palmer, 2006). Epididymal cysts and spermatoceles can manifest as nontender extratesticular masses but are characteristically smooth and round and located within the epididymis. A scrotal ultrasound scan can differentiate these physical examination findings further.

Varicoceles (varicosities of the internal spermatic vein) almost always occur in the left scrotum and are bilateral in about 10%. Varicoceles should always be palpated with the boy standing and shown to drain when the child is supine. Grading is as follows: grade 1, palpated with Valsalva; grade 2, palpated without Valsalva; grade 3, visible through the skin without Valsalva. If the right side only is involved or if the varicocele does not decompress when the boy is supine, a possibility exists that a retroperitoneal tumor is present and compressing the vein.

Penile Examination

In a newborn, the foreskin is adherent to the glans. These glanular adhesions should not be separated, and the glans need not be inspected if the parents do not desire a circumcision. Glanular preputial adhesions usually separate before age 4 but may persist in some boys for longer periods. **In the absence of balanitis or UTI, the prepuce should not be retracted but allowed to separate naturally (Imamura, 1997).** If symptoms do develop, topical corticosteroids have been used successfully as an alternative to circumcision in some boys with adherent foreskin (Chu et al, 1999; Monsour et al, 1999; Orsola et al, 2000; Elmore et al, 2002).

The position of the urethral meatus is almost never abnormal in the uncircumcised penis with a circumferential foreskin. If the ventral foreskin is short or absent, or if there is a ventral or dorsal curvature, the boy should not be circumcised in the nursery by the obstetrician or the pediatrician and should be re-examined as soon as possible by the urologist to determine whether hypospadias or epispadias correction may be needed. The presence of a midline dimple on the ventral penile shaft should lead one to suspect a diagnosis of hypospadias, despite a normal-appearing foreskin. The severity of hypospadias is based on the position of the urethral meatus, the presence or absence of penile curvature, and the degree of ventral penile shaft skin coverage. Occasionally, when the foreskin is pulled back before a circumcision, the distal urethra and urethral meatus are enlarged (hypospadias variant—megameatus intact prepuce). If a megameatus is identified before circumcision in a newborn, the circumcision should be cancelled. The foreskin may be removed at the time of the urethral repair. However, because normal spongiosum is present on the ventral surface of the penis, repair of the urethra is not usually difficult even after a circumcision has been performed (Duckett and Keating, 1989).

Stretched penile length and girth should be measured. If the penis in a full-term infant is less than 2.0 cm, micropenis should be suspected; a karyotype should be performed, and the hypothalamic-pituitary-testicular axis should be assayed. **The penis should be examined in relation to the scrotum for evidence of penile concealment, buried penis, or webbed penis.** In these conditions, the penis is of normal size but buried or concealed beneath a prominent pubic fat pad; trapped by a narrowed, more proximal preputial ring; or tethered to the scrotum. If the penile shaft skin is shortened, correction may require a rotational flap of inner preputial skin to provide additional coverage for the ventrum of the penis after release of the narrowed preputial ring. If a newborn clamp circumcision is performed, more penile shaft skin than indicated is often removed, resulting in a scar and sometimes a secondary trapped penis. If there is encroachment of the scrotum onto the penile shaft, circumcision should be deferred until it can be done freehand in the main operating room under a general anesthetic, usually at 4 to 6 months of age (Casale et al, 1999; Williams et al, 2000).

Female Perineal Examination

Examination of the perineum in female infants and young girls should include examination of the urethral meatus, vaginal

introitus, and anus. An easy way to examine the perineum is to grasp the labia majora gently and pull outward and slightly lateral (see Fig. 125-1). This maneuver tends to define the various perineal folds better and provide for a consistent examination in nearly all cases (Redman, 1982). The clitoris is examined for evidence of hypertrophy that may be suggestive of DSD. Additionally, an introital mass should be examined for site of origin, laterality, symmetry, and signs of infection or irritation. Placing a small feeding tube into the urethral meatus can help distinguish between an asymmetrical prolapsed ureterocele or the circular edema and congestion associated with urethral prolapse. Skene duct cysts are paraurethral in location with a bulging whitish mass superior to the vagina and may manifest with signs of maternal estrogen effects, such as breast enlargement and edema of the vaginal introitus (Soyer et al, 2007). An imperforate hymen in infancy generally appears as a midline bulging, pearly white membrane.

In an adolescent girl, the examination may be performed with the mother present if the adolescent is in agreement. In general, bimanual examination in an adolescent girl is best performed in the operating room in the dorsolithotomy position. In the office, the girl can be examined in a frog-leg position. Gently spreading the labia majora in an inferior direction allows for inspection of the clitoral area and usually of the introitus. The vestibule is assessed for any evidence of discharge. The hymen should be inspected as well as the introitus. **An imperforate hymen may result in hydrometrocolpos and a lower abdominal mass.** In older girls, a small speculum may be used to evaluate the cervix and vaginal canal. Palpation of the vaginal walls and cervix and bimanual examination of the uterus completes the examination. A Valsalva maneuver may allow adequate assessment of the introital vaginal area. Vaginal discharge can be associated with vaginal voiding and is particularly common in children who hold the urine and subsequently dribble urine into the vagina. Treatment of dysfunctional voiding results in reduced vaginal drainage. Vaginal bleeding in a preadolescent girl may result from foreign bodies such as wadded toilet paper trapped in the vagina. Occasionally, other foreign bodies inserted intentionally or accidentally may be found.

Extended Physical Examination

In addition to the abdominal and perineal examination, an examination of the back should always be performed. The lower back should be examined for any evidence of presacral dimpling or other cutaneous markers of occult spinal dysraphisms. **An “atypical” presacral dimple may indicate spina bifida or cord tethering if the dimple is off center, more than 2.5 cm from the anal verge at birth or deeper than 0.5 cm (Soonawala et al, 1999).** In a series of 207 neonates with sacral and presacral cutaneous stigmata, 40% of patients with atypical dimples were found to have occult spinal dysraphism (Kriss and Desai, 1998). Other skin markers that suggest occult spinal abnormalities include subcutaneous lipoma, dermal sinus, tail, or a localized hair tuft (hypertrichosis) (Fig. 125-3). A combination of two or more of these congenital midline skin lesions is the strongest marker of occult spinal dysraphism (Gugisberg et al, 2004). We recommend an ultrasound scan of the lumbosacral spine in a newborn if any of these conditions exists (Unsin et al, 2000; Hughes et al, 2003). In the case of equivocal ultrasound studies and in children older than 6 months, we order MRI for a complete evaluation. A brief evaluation of the upper and lower extremities and of the back is performed for any evidence of asymmetry, length discrepancy, or misalignment of the spine.

If a neurologic examination is indicated, the examination should begin with observation of the child at the outset of the visit. Delays in development (see Table 125-4) often are identified by simple observation. A note is made of the level of alertness of the pediatric patient. Factors affecting the alertness of a newborn include the time of the last feeding, room temperature, and gestational age. One should suspect an underlying metabolic or infectious cause in cases of decreased alertness. Identification of a sensory level in association with a spinal cord lesion can be very difficult in an infant.

Figure 125-3. Clinical aspects of congenital median lumbosacral cutaneous lesions. **A**, Ulcerated hemangioma centered on a dermal sinus and deviation of the gluteal furrow. **B**, Isolated port-wine stain. **C**, Human tail. **D**, Faun tail. (From Guggisberg D, Hadj-Rabia S, Viney C, et al. Skin markers in occult spinal dysraphism: a review of 54 cases. *Arch Dermatol* 2004;140:1109–15.)

Differences in color or temperature can sometimes be observed, with the skin drier and cooler below the level of the cord lesion. Children older than 4 to 5 years are often capable of detailed sensory testing; however, success depends on the ingenuity and patience of the examiner. A child with a low spinal cord lesion may have a patulous anus and absence of contraction of the anal sphincter when stimulated in the anal region by a sharp object (anal wink). Changes in bladder function, such as new-onset urinary incontinence, may indicate a spinal cord lesion.

Often, the urologist may encounter signs of nonurologic or systemic illnesses during the physical examination. In an infant, generalized edema may occur with prematurity or hypoproteinemia. Localized edema suggests a congenital malformation of the lymphatic system. When confined to one or more extremities, edema may be a presenting sign of coarctation of the aorta in association with Turner syndrome. Vasomotor instability and decreased peripheral circulation are revealed by a red or purple color in a crying infant. Scattered petechiae in the infant may be present in the scalp and face after a difficult delivery. Café au lait spots are uniformly hyperpigmented, sharply demarcated macular lesions, the hues of which vary within the normal degree of pigmentation of the individual. These may be dark brown in African-American children. They may vary in size and may be large, covering a significant proportion of the trunk or limb. One to three lesions are common in normal children. Approximately 10% of normal children have café au lait macules. They may be present at birth or develop during childhood. If there are five or more spots each more than 5 mm in diameter in prepubertal patients or six or more spots more than 15 mm in postpubertal children, neurofibromatosis 1 (von Recklinghausen disease) should be suspected.

An exceptionally large head can be familial but may also suggest hydrocephaly, a storage disease, achondroplasia, cerebral gigantism,

neurocutaneous syndrome, or an inborn error of metabolism. Dysmorphic features such as broadened epicanthal folds, widely spaced eyes, micrognathia, and low-set ears are often associated with congenital syndromes that may suggest a genitourinary problem. Preauricular sinuses and pits may be the result of imperfect fusion of the tubercles of the first and second branchial arches. These anomalies may be unilateral or bilateral, may be familial, are more common in females and blacks, and sometimes are associated with other anomalies of the ears and face. Preauricular pits are present in bronchio-otorenal dysplasia, an autosomal dominant disorder that consists of external ear malformation, bronchial fistula, hearing loss, and renal anomalies. Macroglossia can be associated with Beckwith-Wiedemann syndrome, which also includes hepatosplenomegaly, nephromegaly, and hypoglycemia secondary to pancreatic beta cell hyperplasia in a large for gestational age infant. These infants are predisposed to a specific subset of childhood neoplasms, including Wilms tumor and adrenocortical carcinoma. Webbing of the neck in a female infant suggests intrauterine lymphedema in Turner syndrome, as do widely spaced nipples with a shield-shaped chest (Stoll and Kliegman, 2000).

The skin, hair, and nails should be evaluated with special focus on congenital or metabolic problems that may be associated with brittle or abnormal hair and nails or abnormal skin dryness (see Tables 125-2 and 125-3 on the Expert Consult website). Supernumerary nipples may occur in a unilateral or bilateral distribution along a line from the anterior axillary fold to the inguinal area. They are more common in African-American infants (3.5%) compared with white infants (0.6%). Accessory nipples may not have an associated areola and may be mistaken for congenital nevi. The association of supernumerary nipples with renal or urinary tract anomalies is controversial, with differing opinions concerning the

need for evaluation of the urinary system (Grotto et al, 2001; Ferrara et al, 2009). At the present time, there is not a consensus guideline that a renal bladder ultrasound scan is or is not recommended in these cases.

KEY POINTS: PEDIATRIC UROLOGIC EXAMINATION

- Renal pathology is the cause of two thirds of neonatal abdominal masses.
- Performing a scrotal examination in the legs-crossed position facilitates palpation of the testes.
- The inner preputial skin is adherent to the glans in infants and should not be forcibly retracted in the absence of balanitis or UTI.
- The lower back should be examined for evidence of cutaneous markers suggestive of occult spinal dysraphisms.

PEDIATRIC LABORATORY EVALUATION

Urine specimens may be obtained in many different ways. In the child who is not potty trained, a bagged specimen, although the most susceptible to contamination, is the easiest and least invasive to obtain. To minimize contamination with fecal or skin flora, a hole is cut in the diaper, and the perineal bag is brought through the hole in the diaper. A parent is instructed to watch the bag, and as soon as urine is noted (which can be easily seen because the bag is visible coming through a hole in the diaper), the bag should be removed. If the specimen is collected in the office, the bag is immediately drained and the urine plated and sent to the laboratory for culture. Using this method, skin contamination of the urine specimen is minimized, and the trauma of catheterization is avoided (Falcao et al, 1999). However, positive cultures must still be confirmed with catheterized specimens to be reliable. In most cases, we encourage catheterized specimens for the diagnostic reliability they provide.

Older children generally can provide a clean midstream urine specimen. Most studies have failed to show any benefit to formal cleansing of the introitus before obtaining the specimen. After a midstream urine specimen is collected, it is sent to the laboratory for urinalysis and culture. **Pyuria is defined as more than 5 white blood cells per high-power field (HPF) for girls and more than 3 white blood cells per HPF for boys.** Infection can occur without pyuria, and, conversely, pyuria may be present without UTI. Consequently, pyuria as an isolated finding is more confirmatory than diagnostic for UTI. Nitrate and leukocyte esterase assays are usually positive in infected urine. However, if the urine has not remained in the bladder for more than 1 hour, the conversion of nitrates to nitrites may not be complete, and the chemical strip may read negative despite the presence of nitrogen-splitting bacteria in the bladder.

If the culture grows more than 100,000 colonies of a single pathogen or if there are 10,000 to 50,000 colonies and the child is symptomatic, a UTI is likely to be present. Infection is possible with lower counts when urine is obtained via catheter or suprapubic aspirate (Ma and Shortliffe, 2004). **White blood cell casts and urinary sediment suggest renal involvement,** but these are rarely identified. If the child is not symptomatic and the urinalysis is normal, it is unlikely that the urine is infected. Microscopic hematuria is common in acute bacterial and viral cystitis. Gross hematuria may be present in viral cystitis but is less common in acute bacterial cystitis. If the child is symptomatic, the urinalysis is suggestive of UTI, and the culture grows more than one organism or less than 100,000 colonies, the clinician may start treatment with an antibiotic that is effective based on the sensitivities after repeating the culture. If a second catheterized culture is negative, the antibiotics are discontinued, and close follow-up is provided. This approach is particularly important in infants who may not demonstrate the usual signs and symptoms of infection that would be present in an older child.

Microscopic hematuria is common in children. Routine office screening with urinalysis for urinary abnormalities is no longer recommended. The actual time of onset for microscopic hematuria is often unknown. Normally, the first indicator is a positive urine strip test for blood. Most strips can detect concentrations of 5 to 10 intact red blood cells per milliliter. This concentration corresponds to 2 to 5 red blood cells per HPF. Improper interpretation of the dipstick, such as delayed reading or cross-contamination of urine from other chemically impregnated pads, may result in false-positive results. The urine should be dipped, the excess urine should be tapped off, and the strip should be read immediately at the recommended time. **Confirmation of microscopic hematuria after a positive dipstick examination requires a microscopic examination of the urine for the presence of red blood cells.** Microscopic hematuria may be defined as more than 5 red blood cells per HPF in at least two of three urinalyses over 2 to 3 weeks. An absence of red blood cells in the urine with a positive dipstick result suggests hemoglobinuria or myoglobinuria. A positive dipstick on a single specimen with microscopic confirmation should be viewed as an indication for further urine testing rather than as diagnostic until persistence is confirmed on subsequent studies.

PEDIATRIC RADIOGRAPHIC EVALUATION

Ultrasonography

Ultrasonography of the kidneys, ureters, and bladder is an extension of the physical examination. Ultrasonography provides a noninvasive evaluation that does not require sedation, ionizing radiation, or contrast agent injection and can be performed at the bedside in critically ill children. Additionally, the body habitus of young children allows for accurate imaging. Older children or children with significant skeletal abnormalities such as severe scoliosis or kyphosis often require other imaging modalities to assess the kidneys and collecting system accurately. A palpable mass within the abdomen can be localized and diagnosed with the aid of ultrasonography performed by a urologist with an interest in pediatrics. The examination should evaluate not only the genitourinary system but also adjacent organs such as the adrenal glands, liver, and spleen. The echogenicity of the parenchyma of the liver and spleen should be used as a comparison to assess the parenchyma of the right and left kidney, respectively. The density of the kidney and of the renal medullary pyramids; the wall thickness and configuration of the collecting system; and the presence or absence of caliectasis, pelvictasis, or ureterectasis all are important indicators of renal and ureteral pathophysiology (Hulbert et al, 1992). The luminal diameter of the ureters, thickness of the bladder wall, and volume of the bladder before and after voiding should be recorded (Palmer, 2006). If hydronephrosis or ureterectasis is present before voiding, the kidneys and ureters should be rescanned after voiding. A skillful ultrasonographer can provide anatomic detail about the insertion of the ureters and the degree of dilation of the ureter and can identify the jet of urine as it enters the bladder (Cvitkovic et al, 2001). Ultrasonography may also be used to measure postvoid residual urine accurately (Coombes and Millard, 1994). Increased thickness of the bladder wall may be suggestive of bladder outlet obstruction from PUV or urethral atresia. Trabeculation within the bladder, bladder diverticulum, and ureteral duplication or ureterocele all are easily identified with ultrasound. Children presenting with a febrile UTI are evaluated with ultrasonography to determine if a structural anomaly is present (Giorgi et al, 2005). **Ultrasonography in the absence of comparison studies or appropriate history cannot by itself distinguish obstructive from nonobstructive hydronephrosis.** A functional study such as a diuretic renal scan or magnetic resonance urography (MRU) is usually required for diagnosis. Ultrasonography is also sensitive in detecting solid renal masses, particularly masses that measure at least 1.5 cm in largest dimension. For smaller renal masses, the ultrasound findings should be considered preliminary and should be confirmed with CT or MRI (Jamis-Dow et al, 1996).

Ultrasonography is also frequently used to examine the scrotum (Diamond et al, 2000). It may also be used to assess blood flow if spermatic cord torsion is suspected and to distinguish between epididymitis and torsion of the appendix testis in cases in which tenderness is localized to the upper pole of the testis. In the setting of acute scrotal pain, Doppler ultrasonography has been reported to have a sensitivity of 78.6% and specificity of 96.9% in diagnosing surgical and nonsurgical scrotal conditions and has replaced testicular nuclear scan to rule out torsion (Blask et al, 2002). However, false-negative ultrasonography can occur and must be confirmed by a careful physical examination. Scrotal masses are evaluated by ultrasonography. Additionally, ultrasonography may be useful in distinguishing hernia from hydrocele or identifying abdominoperineal hydroceles (Finkelstein et al, 1986). However, one should not routinely perform ultrasonography or other imaging modalities in the evaluation of boys with cryptorchidism because these studies rarely assist in decision making. Ultrasonography is inadequate for routine use, with sensitivity and specificity to localize nonpalpable testis of 45% and 78%, respectively (Tasian and Copp, 2011).

When ultrasonography is used as a first-line test in suspected occult spinal dysraphism, optimal timing of the spinal ultrasound scan is before 6 months of age. Ossification of the posterior elements after 6 months of age prevents an adequate acoustic window. Agreement between ultrasonography and MRI is good, particularly for the detection of the low-lying spinal cord (90%) (Hughes et al, 2003).

Ultrasonography is also performed during routine prenatal care. The kidneys and bladder can be visualized at 15 weeks of gestation. Further details including the renal pelvis and corticomedullary differentiation are detectable after 20 weeks of gestation (Sty and Pan, 2006). Hydronephrosis remains one of the most common abnormalities detected by prenatal sonography (Fig. 125-4). After delivery, a repeat renal and bladder ultrasound scan is performed to assess the collecting system further and determine the appropriate evaluation and treatment if necessary.

Voiding Cystourethrography

VCUG is used to identify VUR, to evaluate the anatomy of the bladder outlet (bladder neck and posterior urethra) during bladder filling and voiding, and to assess the presence of residual

urine after micturition. Additional information regarding trabeculation of the bladder, bladder diverticula, and presence or absence of urachal abnormalities may be identified with a fluoroscopic VCUG (Fernbach, 2000; Goldman et al, 2000; McDonald et al, 2000). The VCUG begins with a plain film, followed by placement of a feeding tube rather than a Foley catheter. The balloon on a Foley catheter may obscure the anatomy of the bladder neck and trigone, particularly at the beginning of the study. The percentage of bladder filling when the reflux is first identified may also be an indicator of potential resolution of VUR. On subsequent examinations, improvement in VUR may be assumed if a smaller percentage of total bladder volume is refluxing into the ureter or if the reflux occurs at a greater percentage of total bladder filling (Mozley et al, 1994). On the plain film, abnormalities of the spine (e.g., sacral agenesis or spina bifida occulta), ribs, and pelvis and the presence or absence of stones within the kidney, ureter, or bladder should be noted. The gas pattern and volume of stool is particularly important in infants and in children with dysfunctional voiding in whom constipation may be an important part of the clinical pattern. Gas should normally be present in the rectum on a plain film by 24 hours of age. The bladder should be drained, and contrast medium should be gently infused. In children in whom a ureterocele is suspected, the first few images during filling of the bladder best demonstrate the ureterocele as a filling defect in the bladder. The bladder is filled slowly, and the child voids. Later filling images may involute a ureterocele, and it may appear as a bladder diverticulum.

Voiding views must be obtained in all cases, but particularly if bladder outlet obstruction such as PUV is suspected. In children in whom VUR is suspected or in patients with an ectopic ureter, cyclic VCUG must be performed in which at least two voiding cycles are completed. In some cases, the ectopic ureter that is draining to the bladder neck must empty for additional contrast material to reflux. If a second voiding cycle is not performed, one might miss reflux into the ectopic system (Hellstrom and Jacobsson, 1999; Polito et al, 2000). It is important to image the bladder neck during voiding in girls as well as boys. The presence of a "spinning top urethra" in a school-aged girl may be an important indicator of dysfunctional voiding (Saxton et al, 1988; Soygur et al, 2004). Vaginal voiding and subsequent emptying (or failure to empty) of the vagina should also be noted, which may be seen on the postvoid views.

In patients with a urogenital sinus, contrast VCUG may be modified to image the urethra and vagina simultaneously (Fig. 125-5). In this study, the urogenital sinus is intubated with

Figure 125-4. Prenatal ultrasound image showing hydronephrosis.

Figure 125-5. Genitogram of urogenital sinus showing confluence of the urethra and vagina (arrow).

a blunt-tipped catheter (which can be made by trimming the cone-shaped end of a feeding tube) and placed against the perineal opening. Contrast medium is injected retrograde to identify the point where the vaginal introitus meets the urethra to form the urogenital sinus. The study also aids in differentiating a cervical dimple from a prostatic utricle. If a cloaca is present, the sinogram provides detail about the position of the rectum, vagina, and urethra and about the point of confluence and the distance to the perineum (Shaul and Harrison, 1997; De Filippo et al, 1999). The distances of these structures help determine the approach required during surgery (Pena et al, 2004).

Renal Scintigraphy

A radionuclide renal scan is measured in two phases: cortical imaging and tubular imaging phase. Most radionuclide agents demonstrate renal tubular and renal cortical binding. Radionuclide studies are best suited to demonstrate changes in tubular or cortical transit that result from abnormalities of renal perfusion, secretion, and filtration. In most cases, the radionuclide study is inferior to CT, MRI, or ultrasonography for demonstration of anatomic alterations. ^{99m}Tc MAG3 is secreted in part by renal tubular function and may be used to approximate relative renal plasma flow. The MAG3 renal scan assists in differentiating obstructive versus nonobstructive dilation of the urinary tract. Proper interpretation of the information obtained from this study requires detailed knowledge of the factors affecting drainage of the upper urinary tract (Shulkin et al, 2008). If detailed imaging of the renal cortex is required to identify renal scarring, ^{99m}Tc DMSA should be used because it is more cortical-retentive, and the kidneys are imaged 3 to 4 hours after the injection (Majd and Rushton, 1992; Piepsz et al, 1999).

Renal scintigraphy scans using gallium-67-labeled or indium-111-labeled leukocytes may be helpful to diagnose and localize the site of pyelonephritis (Yen et al, 1999; Velasco et al, 2004). These techniques may be used to identify and guide therapy for children with focal segmental bacterial pyelonephritis in whom the duration of therapy is uncertain. In a prospective study by Yen and associates (1999), gallium-67 renal scan was more sensitive than DMSA scan in the diagnosis of acute pyelonephritis, especially in differentiating new lesions from old ones. These scans are particularly useful in patients with abnormal renal anatomy or in patients with diminished renal function in whom the DMSA scan may be less specific.

Computed Tomography

CT is used judiciously in specific pediatric clinical settings owing to the ionizing radiation required. CT is rarely used in neonates or infants with the exception of evaluation of a retroperitoneal or pelvic mass. Conversely, CT with intravenous contrast enhancement is the current imaging modality of choice for evaluation of pediatric abdominal trauma. Additionally, spiral CT in most cases has replaced the intravenous pyelogram (IVP) as the first-line study in children in whom stone disease is suspected; however, the relative value of CT compared with ultrasonography must be considered based on the clinical scenario because of the radiation burden of CT. In addition, CT with or without contrast medium enhancement is particularly important as an adjunct in children with suspected focal segmental bacterial pyelonephritis. CT is also particularly important in the diagnosis and staging of solid tumors of the chest and abdomen. Contrast medium-enhanced CT is particularly useful in cases of nephroblastomatosis, in which ultrasound shows little displacement of the renal capsule. It must be kept in mind that radiation doses from CT are cumulative over the life of an individual (Frush et al, 2003). With sufficient clinical information, the radiologist may be able to recommend other imaging modalities (e.g., ultrasonography, MRI) that do not use ionizing radiation.

Magnetic Resonance Urography

Although still expensive as an individual radiologic study, MRU may provide the best information about the anatomy and function of the genitourinary tract from a single study. Advantages of MRU include the avoidance of ionizing radiation, use in patients with impaired renal function, and higher quality contrast and spatial resolution in any plane relative to other imaging modalities (Wille et al, 2003; Grattan-Smith, 2008) (Fig. 125-6). If obstruction of the urinary tract is suspected, gadolinium followed by furosemide can be administered to assess renal drainage better. MRI with gadolinium should not be performed in a full-term infant before 2 months of age. Antenatal MRI is used to diagnose UPJ obstructions, ectopic ureters, abnormal ureteral buds associated with renal agenesis, and cloacal exstrophy in the fetus (Maas et al, 1997; Matsuki et al, 1998; Wille et al, 2003). When antenatal ultrasonography is equivocal, antenatal MRU provides additional anatomic detail especially in the diagnosis of ureteral pathology (Kajbafzadeh et al, 2008). Limitations of MRU at the present time include high costs and the requirement for sedation or anesthesia in most young patients. MRI has also been used in the evaluation and identification of an impalpable testis (Yeung et al, 1999; Lam et al, 2001). MRI with or without angiography has been more widely used with greater sensitivity and specificity, but its use is deterred by cost, low availability, and need for anesthesia (Kanemoto et al, 2005; Kantarci et al, 2010). At the present time, there is no radiologic test that can conclude with 100% accuracy that a testis is absent. In the workup of suspected renovascular hypertension, gadolinium-enhanced magnetic resonance angiography is a noninvasive modality with comparable accuracy to digital subtraction angiography (Hacklander et al, 2004).

Intravenous Pyelography

Because newer imaging techniques are now available, the IVP is included here for historical completeness. The plain film of the

Figure 125-6. Magnetic resonance urogram showing partial ureteral duplication with an ectopic ureter past the bladder neck (found to enter the vagina).

abdomen should be inspected for calculi, spinal abnormalities, and an abnormal intestinal gas pattern. The nephrogram phase of the IVP identifies mass effects within the kidney and the presence or absence of scarring after pyelonephritis. Subsequent views can assess sequentially the anatomy of the renal cortex, calyces, fornices, renal pelvis, ureters, bladder, and urethra (Smellie, 1995). Subtle anatomic variations in normal anatomy of the renal calyces or of the UPJ that may be confusing on ultrasonography were previously clarified with the IVP. Today, the full anatomy may be elicited with CT urography or MRU.

KEY POINTS: PEDIATRIC LABORATORY EVALUATION AND RADIOGRAPHIC EVALUATION

- Microscopic hematuria diagnosed on dipstick evaluation should be confirmed with microscopic examination of the urine.
- Ultrasonography cannot definitively distinguish obstructive from nonobstructive upper tract urinary dilation.
- A VCUG should include multiple voiding cycles with images of voiding views.
- Nuclear medicine evaluation is increasingly used in the evaluation of patients with VUR.
- CT should be used judiciously in children because of the risks of ionized radiation.
- MRU provides functional and anatomic information about the entire urinary tract.

PEDIATRIC URODYNAMIC EVALUATION AND BIOFEEDBACK TRAINING

A well-equipped urology office has a urodynamic suite as part of the overall complex. Modern urodynamic systems allow accurate measurements of the intravesical pressures before, during, and after bladder contraction. From these measurements, estimates of bladder compliance and bladder outlet resistance may be made. With this information, the pediatric urologist may assess whether the bladder stores at pressures low enough to prevent renal damage and empties well enough to prevent UTI. The addition of fluoroscopic monitoring of the bladder and upper tracts during urodynamics greatly adds to the information garnered from the urodynamic study. However, the video-urodynamic suite needs to be located within a lead-lined room, which may preclude placement in every office.

Biofeedback training designed to help a child to improve bladder emptying may also be performed in the office. Biofeedback sessions should be done in a room that is separate

from the urodynamic suite because in most cases a different population of patients requires biofeedback training than would undergo urodynamic study (Yamanishi et al, 2000; Schulman, 2004). Biofeedback, if done properly, is time-consuming. The child must be relaxed and motivated for the session to be effective. Awareness of the pelvic floor muscle and urinary sphincter is a key factor to achieve successful biofeedback treatment. Biofeedback incorporating interactive computer games is available, with success rates approaching 90% after a mean of 4.9 sessions (Herndon et al, 2001).

OFFICE SURGICAL PROCEDURES

Successful outpatient surgery with local anesthetic depends on cooperation from the parent as well as the child. The balance is understanding the convenience of having the procedure in the office versus the advantage or risk of a general anesthetic in the main operating room. We believe many infants weighing less than 10 pounds may easily undergo an office circumcision with an anesthetic cream sometimes combined with injected local anesthetic (Hoebeker et al, 1997). In a meta-analysis by Brady-Fryer and colleagues (2004), dorsal penile nerve block was most effective at reducing circumcision pain compared with EMLA (eutectic mixture of local anesthetics) cream or placebo. We rarely perform office circumcision in older children. Infants older than 3 months are too big to be easily restrained, and the risk of bleeding postoperatively and skin separation is considerable if the skin edges are not sutured.

Numerous techniques may be used in the clinic for circumcision, including a Plastibell, Mogen clamp, and Gomco clamp. We use the Gomco clamp (Fig. 125-7A), which is a three-component device that includes a bell that fits over the glans of the penis and separates the glans from the inner preputial skin (Guazzo, 1999; Amir et al, 2000; Wan 2002). The clamp is applied, and the foreskin is trimmed away from the clamp. If the clamp is left in place for a considerable amount of time (usually about 5 to 10 minutes), there is very little separation of the skin postoperatively. If desired, a small nonstick bandage is placed beneath a transparent adhesive dressing. The bandage is removed the next day. The boy's parents are instructed to apply petroleum jelly to the incision during the healing period.

Complications after neonatal circumcision include bleeding, wound infection, meatal stenosis, and secondary phimosis (cicatrix) resulting from removal of insufficient foreskin or removal of insufficient inner preputial skin (Fig. 125-7B). Potentially serious complications are rare but include death, sepsis, amputation of distal part of the glans, removal of excessive foreskin, and urethrocutaneous fistula (Baskin et al, 1997; Hutcheson, 2004; Krill et al, 2011). After a circumcision, the cut edge of the preputial surface may occasionally graft to the inflamed glans tissue forming

Figure 125-7. A, Gomco circumcision. B, Postcircumcision cicatrix (arrow).

a preputial-glanular bridge that may be incised in the office after application of local anesthetic cream and/or injection of local anesthetic. After administration of local anesthesia, the skin bridge is crushed with a hemostat clamp, and the skin bridge is sharply incised. No suturing is required in most cases. This procedure is easy and virtually painless. After the procedure, the parents apply petroleum jelly to the incised edges to prevent readherence.

Meatal stenosis is common after circumcision. It may result from contraction of the meatus after healing of the inflamed, denuded glans tissue that occurs after retraction of the foreskin or from damage to the frenular artery at the time of circumcision (Persad et al, 1995; Upadhyay et al, 1998). If the narrowing is pronounced enough to cause deflection of the urinary stream or dysuria, a meatotomy is indicated.

To perform a meatotomy in the office, an anesthetic cream is applied for 60 minutes and, if desired, additional lidocaine with 1% epinephrine may be injected with a 26-gauge needle to provide a small wheal at the ventrum of the urethral meatus. The ventral edge of the urethral meatus is clamped, and a small wedge of the scarred tissue is crushed with a straight hemostat and sharply excised. After the procedure, the parents are advised to apply a thin petrolatum ointment into the meatus to lubricate the cut edges and dilate the meatus twice daily for 2 weeks and as needed thereafter. Postoperatively, infants may be seen 2 to 3 months later to assess the result.

If a VCUG is required or if dysuria associated with vaginal pooling of urine contributes to a dysfunctional voiding pattern, we have occasionally separated labial adhesions in the office. These membranous adhesions are easy to separate on the midline with petroleum jelly on the physician's gloved fingertip, a probe, or the tip of a curved hemostat. A local anesthetic cream is applied to the labia before the procedure in hopes of easing the discomfort, which is minimal. After lysis of the adhesions, the child's parent must separate the labia and apply lubricating ointment such as petroleum jelly at least twice a day for 2 to 6 weeks while the labial tissue matures. With diligent postoperative care, recurrence is rare.

KEY POINTS: PEDIATRIC URODYNAMIC EVALUATION AND BIOFEEDBACK TRAINING AND OFFICE SURGICAL PROCEDURES

- A well-equipped urology office has a urodynamic suite and biofeedback training suite.
- Most infants weighing less than 10 pounds may easily undergo an office circumcision with an anesthetic cream combined with injected local anesthesia.
- Petroleum jelly is applied after circumcision, urethral meatotomy, or lysis of labial adhesions to prevent complications.

SUMMARY

The final goal of the surgical care of children is to ensure as normal an adult life as possible. For boys with PBS or PUV and for children of either sex born with bladder or cloacal exstrophy, the pediatric urologist should continue to act as consultant even after the child enters adulthood. **As children grow into adults, the pediatric team must develop a liaison with a skilled, interested adult urologic team. Using this method, a lifetime plan of care may be designed and carried out to ensure well-coordinated urologic therapy that addresses the complicated problems unique to this group of boys and girls.**

Safety

Nonionizing Modalities

Imaging has long been a critical component in urologic investigation and diagnosis for adults and children. However, with advances in imaging modalities and the unique urologic and psychosocial concerns of children, imaging in the pediatric setting must be viewed in the proper light. For instance, studies that are routine and tolerable in adults may require anesthesia or specially trained technicians in children. Doses may need to be adjusted and equipment may need to be available that is suitable for a child's smaller body. Urologists treating children need to be aware of these age-specific differences for the purposes of ordering, reading, and interpreting these tests. We describe the assets and liabilities of these tests with regard to common pediatric urogenital inquiries. A more in-depth look at the physical and technical details of each modality can be found in Chapters 2 and 3; only aspects unique to children are reiterated here.

SAFETY

Having decided on the necessity of imaging to evaluate the urinary tract, it is important in imaging of children to consider the doses of radiation given per study, the predictable need for future studies of similar radiation dose, the need for contrast agents, and the need for anesthesia or sedation to obtain adequate images. Although quantifying the radiation risk accurately for the individual patient is challenging, there is consensus that one should practice under the ALARA principle—as low as reasonably achievable (Don et al, 2013; ICRP et al, 2013). Because it is not possible at the present time to predict an individual's susceptibility to radiation effects, all patients should be treated as radiation sensitive (Kleinerman, 2009). We address the risks of radiation in this chapter only briefly because this topic is discussed in more depth in Chapter 2.

Although nonionizing radiation is considered a safer alternative, it is not without risk. When substituting computed tomography (CT) with magnetic resonance imaging (MRI), many children require anesthesia or sedation because of the longer acquisition times (Arthurs et al, 2012). This risk of sedation or anesthesia is typically higher than the risk of nephrogenic systemic fibrosis secondary to the use of gadolinium in a child with poor renal function or in the setting of immature renal function in a neonate (Thomsen et al, 2007; Karcaaltincaba et al, 2009). However, the small risk of contrast-induced nephropathy in children with poor renal function similarly exists with CT (Thomsen, 2007). Both contrast materials pose a higher, although still quite small, risk of allergic reaction (Arthurs and Bjørkum, 2013). The radiofrequency pulses creating the electromagnetic field can cause patient heating that must be monitored to prevent hyperthermia, which has been reported, although rarely (Kussman et al, 2004; Wang et al, 2007). The long-term safety of MRI exposure has been questioned based on revealed changes in gene expression related to magnetic field exposure (Bonassi et al, 2007; Kimura et al, 2008; Simi et al, 2008). Although no human data have been produced,

Ionizing Modalities

it is recommended to avoid fetal MRI in the first trimester. Ultrasonography has not been shown to cause gene expression changes and is regarded as safe at all ages.

Ionizing radiation is considered more harmful in children than in adults because of the greater radiosensitivity of developing tissues and potential for higher cumulative doses over the child's lifetime (Arthurs and Bjørkum, 2013). In children, the stochastic effects of repeated exposure (i.e., internal cell injury) can result in radiation-induced malignancies after a prolonged latent period. When evaluating the literature on ionizing radiation risk, care must be taken to determine if the risk reported is estimated, modeled, or measured from clinical practice. Variations in technique and patient age and size and varied intervening studies during the required long study intervals can make measured studies difficult to interpret. Acknowledging these significant limitations in determining ionizing radiation risks in children, there appears to be reasonable evidence to suggest a dose-related risk in children and in utero (Arthurs and Bjørkum, 2013). However, quantifying this risk is extremely difficult with the currently available data. Considerable work is being done to reduce radiation doses of individual tests, while still maintaining the necessary diagnostic accuracy to provide good care. Likewise, better medical decision making and offering nonionizing alternatives have gained momentum.

NONIONIZING MODALITIES

Ultrasonography

Prenatal Imaging

Various urologic conditions can be diagnosed prenatally with near certainty using sonography to investigate the presence and quality of the renal cortex, laterality of the abnormality, position of the abnormality within the abdomen and its association with other organs, and the presence of a normal amount of amniotic fluid (Dias et al, 2014). The features of a normal urinary tract include renal cortex that is isoechoic or slightly hypoechoic to the liver; the presence of discrete interfaces between the cortex and the medulla; the absence of cortical cysts; and the absence of masses or dilation of the collecting system, ureters, or bladder. Additionally, bladder cycling might be observed if patience is exercised, and attention should be placed on the placement of the umbilical cord and completeness of the anterior abdominal wall. The following survey of the types of abnormalities encountered is organized by salient features seen on prenatal ultrasound scans.

Hydronephrosis, Obstructive Uropathies, and Cystic Renal Lesions. Dilation of the renal collecting system and parenchymal cysts are the most common findings on prenatal sonography (Blyth et al, 1993). A differential diagnosis list that considers most possibilities includes hydronephrosis (obstructive and nonobstructive), multicystic dysplastic kidney, polycystic kidney disease (autosomal recessive and autosomal dominant), and cystic nephroma.

Although it has been debated that all cases of hydronephrosis represent obstruction in some form or another, most hydronephrosis follows a benign natural history, such that improvement or resolution is seen. More profound developmental abnormalities manifest as moderate to severe hydronephrosis because of high-grade obstruction, and the transition between dilated and nondilated urinary tract localizes the site of obstruction to the ureteropelvic junction, ureterovesical junction, or urethra. For example, a thickened bladder and dilated posterior urethra known as the “keyhole” sign is highly suggestive of a posterior urethral valve (Fig. 126-1). Cystic disease can mimic hydronephrosis on initial inspection but can be discriminated from it ultimately because cysts do not communicate with one another, but dilated calyces and pelvis do. In the case of multicystic dysplastic kidney (MCDK), the cysts are of varying sizes and randomly distributed throughout the renal parenchyma in addition to not communicating with one another and are unilateral (Fig. 126-2A). By contrast, bilateral cystic lesions should raise concern for polycystic kidney disease, of which there are two types: autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD). ARPKD is characterized by enlarged and homogeneously hyperechoic parenchyma that results from dilation of the collecting tubules (Fig. 126-2B). ADPKD is identified by the presence of enlarged

kidneys in which the parenchyma is almost replaced by cysts. A multilocular cystic nephroma is a benign cystic renal tumor that shares features with MCDK and cystic Wilms tumor. It also manifests as noncommunicating cysts of varying sizes but generally has more parenchymal tissue than MCDK. Multilocular cystic nephroma is a tumor of infancy, whereas (cystic) Wilms tumor occurs in children around 2 to 4 years old.

Midline Pelvic Cysts. A differential diagnosis list includes hydrometrocolpos (urogenital sinus anomalies), ovarian cyst, distended bladder, and urinary ascites. Hydrometrocolpos is distention of the uterus and vagina with mucus or blood and results from vaginal obstruction secondary to imperforate hymen, vaginal atresia, transverse vaginal septum, or retrograde flow of urine in urogenital sinus and cloacal malformations (Hill and Hirsch, 1985; Banerjee et al, 1992) (Fig. 126-3).

Renal and Abdominal Solid Masses. A differential diagnosis list includes neuroblastoma, congenital mesoblastic nephroma, Wilms tumor, renal vein thrombosis, renal artery thrombosis, adrenal hemorrhage, and rare renal solid tumors (rhabdoid, clear cell, angiomyolipoma) (Fig. 126-4).

Abdominal Wall Defects. Although generally quite rare, bladder exstrophy and prune-belly syndrome represent defects in formation of the abdominal wall with associated urogenital abnormalities.

Figure 126-1. Prenatal sonogram demonstrating bilateral (A and B) hydronephrosis and hydro-ureter and the thickened bladder and “keyhole” sign (C) typically associated with bladder outlet obstruction, in this case of posterior urethral valve.

Figure 126-2. A, Prenatal sonogram demonstrating randomly distributed cortical cysts typically seen in multicystic dysplastic kidneys. B, Prenatal sonogram demonstrating homogeneously hyperechoic renal parenchyma of autosomal recessive kidney disease.

Figure 126-3. A, Prenatal sonogram performed for oligohydramnios in a 34-week female fetus demonstrating dual pelvic cystic structures below a dilated bladder. B, Postnatal sonography confirms the pelvic structures to be hemivaginas. C, Cystogram confirms the diagnosis of cloacal anomaly because the hemivaginas, dilated bladder, and distal colon are opacified with contrast medium injected into a single perineal opening. Bl, bladder; Co, colon; V1, hemivagina; V2, hemivagina.

Figure 126-4. Nephroblastoma (Wilms tumor) detected by sonography.

Classic bladder exstrophy can be identified when the bladder is not visualized and instead possibly observing an irregular lower abdominal wall and inferiorly placed umbilicus. Prune-belly syndrome is suggested by observing hydronephrosis and hydroureter, a distended bladder, and the absence of testes in the scrotum in a male fetus (Fig. 126-5).

Upper Tract

It is important to recognize the subtle differences in the sonographic appearance of the kidney in a newborn compared with older children and adults. The distinct corticomedullary differentiation combined with a slightly hyperechoic renal parenchyma in infants compared with a mature kidney can be mistaken for hydronephrosis in a newborn by an inexperienced clinician (Fig. 126-6). Also, the degree of hydronephrosis can be underestimated in an early postnatal sonogram (i.e., up to 2 days after birth) and/or in the setting of dehydration.

Sonography is the ideal initial modality for identifying pediatric hydronephrosis and hydroureter. Many parameters have been proposed for standardization of hydronephrosis reporting, but variation among specialties persists (Zanetta et al, 2012). The Society

for Fetal Urology classification system is the most widely used by pediatric urologists and is based on the extent of calyceal dilation, involvement of minor calyces, and parenchymal thinning (Nguyen et al, 2010) (Fig. 126-7). Other pediatric urologists use a measure of renal pelvic anteroposterior diameter or a combination of classification systems to aid in decision making and risk stratification (Timberlake and Herndon, 2013). These inconsistencies in hydronephrosis reporting make it paramount that the clinician reviews the actual images when making clinical decisions.

Sonography in the setting of urinary tract infection (UTI) is typically used as an initial screening test to rule out obvious anatomic abnormalities that may warrant further investigation. It has been found to be very sensitive for the detection of significant renal abnormalities except for uncomplicated duplication anomalies and focal renal scarring (Horgan et al, 1984; Jequier et al, 1985; Kangarloo et al, 1985; Leonidas et al, 1985). It is often used to complement voiding cystourethrography (VCUG). Because clinical signs and symptoms suggest whether treatment should be intravenous or oral as well as its duration, imaging is generally performed in an acutely ill child only when the patient fails to improve or worsens despite appropriate antibiotic treatment. Most imaging algorithms are applied after treatment and in the interest of identifying risk factors for recurrent UTIs and anatomic abnormalities that increase the risk of complicated UTIs and associated renal injury. For patients requiring hospitalization, it is often advocated that screening sonography be performed before discharge to exclude obstruction. Otherwise, imaging is delayed until after discharge. In the absence of vesicoureteral reflux (VUR), hydronephrosis revealed by sonography can be evaluated further by diuretic renography, which in combination reliably localizes the site of obstruction in all cases (Shalaby-Rana et al, 1997; O'Hara, 2002). Despite its many advantages, standard gray-scale sonography is inferior in the detection of acute pyelonephritis or renal scarring compared with dimercaptosuccinic acid (DMSA). A normal sonogram is insufficient to risk stratify a child with acute pyelonephritis and is not a good predictor of VUR (Nelson et al, 2014). Advances to improve sonographic accuracy in detection of acute pyelonephritis are promising (McArthur and Baxter, 2012).

Contrast-enhanced and noncontrast voiding sonography is proving its accuracy for detection of VUR, but the technique is still in its infancy and not yet widely performed (Papadopoulou et al, 2009; Darge, 2010; Fallah et al, 2012). It uses the detection of echogenic microbubbles tracked in real time during voiding and bladder cycling. A five-point grading system has been developed similar to that used for VCUG (Darge and Troeger, 2002). Voiding

Figure 126-5. A, Prenatal sonography and magnetic resonance image of male fetus with classic bladder exstrophy. The kidneys were normal, and no hydroureter was seen, but the cord inserted low into the abdomen, the bladder was not visualized in pelvic views, and the phallus was short. B, Prenatal sonogram of male fetus with prune-belly syndrome demonstrating the presence of a high amniotic fluid index (AFI). Although prune-belly syndrome and posterior urethral valve share sonographic features, such as hydronephrosis and hydroureter, this case did not demonstrate a thickened bladder wall and distinct “keyhole” sign, which are typical of posterior urethral valve. Also, the testes were not seen in the scrotum, which is another prenatal clue that the diagnosis was prune-belly syndrome.

Figure 126-6. A and B, Postnatal sonograms demonstrating the high-contrast corticomedullary differentiation typical of the newborn kidney, which might be mistaken for dilated calyces. C, Renal sonogram in an older child for comparison.

sonography is associated with a higher cost because it is time-consuming, but it is promising as a nonionizing option for detection and monitoring of VUR (Piscitelli et al, 2008).

Children with stone disease will likely have a lifetime of screening and point-of-care imaging so an intentional effort to minimize the amount of radiation is needed. The parent and older child should be well informed of these intentions and play an active role in this plan especially if visiting an unfamiliar emergency facility or physician. Ultrasonography might be sufficient as an initial screening test or follow-up imaging in most children with acute renal colic from stones, as opposed to obtaining a CT scan or kidney-ureter-bladder film reflexively. Sonography is ideal for detecting hydronephrosis and hydroureter, which can direct further imaging if the calculi cannot be definitively identified. It can also reliably detect intraparenchymal calculi and nephrocalcinosis (Fig. 126-8A). On sonography, calculi appear echogenic with shadowing, not to be confused with peripelvic fat, which is echogenic without shadowing. A “twinkling” artifact can also be seen when using color Doppler to distinguish calculi from other hyperechoic signals (Lee et al, 2001; Lu et al, 2013) (Fig. 126-8B).

Although standard renal ultrasonography is an anatomic study, inference of function has been proposed using various techniques

and measurements (Grenier et al, 2013; Inchingolo et al, 2013; Peters et al, 2013). The main clinical question in the setting of hydronephrosis is whether it is caused by obstruction, is caused by VUR, or is a normal variant. Hydronephrosis secondary to obstruction can be evaluated using functional studies only. Hydronephrosis secondary to VUR is discussed later in this chapter. In the setting of bilateral hydroureteronephrosis, a thickened bladder, and poor emptying, VCUG should be performed to rule out a posterior urethral valve (Fig. 126-9). Otherwise, diuretic renography is the gold standard. There are promising advancements using computer-aided shape analysis and ultrasound elastography to measure the dilated collecting system and renal parenchymal or pelvic tension as an indirect measure of obstruction (Grenier et al, 2013; Kang et al, 2013; Peters et al, 2013). If these sonographic techniques prove accurate in assessing function, other ionizing techniques can be avoided or reduced dramatically.

Lower Tract

Bladder. Bladder sonography can be performed to assess anatomy and basic function. From an anatomic standpoint, sonography can be used to detect ureteroceles, large diverticula, bladder calculi, bladder debris, or suspicious bladder masses (Fig. 126-10). Bladder wall thickness is a more difficult proposition because this changes significantly with bladder volume and age. Many authors have tried to standardize measurements of the bladder wall and index this to volume to predict pathology or define normality, but this has not gained widespread use because of its complexity and variability (Kaefer et al, 1997; Yeung et al, 2004; Bright et al, 2010). Regardless, a grossly thickened bladder on sonography should be viewed with suspicion if the clinical picture is consistent with voiding dysfunction (Yeung et al, 2007). Simple functional assessment of bladder emptying can be quantified by measuring volumes before and after voiding.

Genitalia. Genital imaging is limited to essentially four basic conditions: acutely painful or enlarged scrotum, testicular and paratesticular masses, cryptorchidism, and ambiguous genitalia. Ultrasonography is always the initial and usually the only imaging modality needed. Overuse of ultrasonography for scrotal conditions is widespread because most scrotal conditions can be diagnosed on the basis of history and physical examination rather than imaging. Likewise, overzealous interpretation of scrotal imaging, especially when in contradiction to the clinician’s physical examination, should be avoided.

In the case of an acutely painful scrotum, color Doppler sonography can be useful in the differential diagnosis of a child with an equivocal clinical examination for torsion (Baker et al, 2000; Dajusta et al, 2013). Surgical exploration should not be delayed if torsion is suspected and waiting to perform imaging would compromise salvageability. Because of reported false-negative and false-positive results using color Doppler sonography, especially in infants, investigators have used high-resolution ultrasonography to image torsion of the spermatic cord itself, known as the “whirlpool” sign (Vijayaraghavan, 2006) (Fig. 126-11). High-resolution ultrasonography was shown to increase sensitivity to 96% (from 76% using color Doppler sonography) and to have 99% specificity (Kalfa et al, 2007). Salvageability of the testicle based on sonographic appearance is difficult to predict except in the setting of no arterial flow and parenchymal heterogeneity, in which case 100% were nonviable at exploration (Kaye et al, 2008).

Other nontorsion scrotal conditions can be seen with color Doppler sonography. Epididymo-orchitis can be visualized as hyperemia of the epididymis and/or testicle (Fig. 126-12). However, this finding on sonography must be correlated with the clinical presentation because it can also be seen in the setting of recent spontaneous detorsion. Torsion of a testicular or epididymal appendage can also be captured by a skilled technician as an upper pole or epididymal hypoechoic and avascular nodule with surrounding hyperemia. Acute idiopathic scrotal edema can be identified by the “fountain” sign or hyperemia of a thickened scrotal wall in the absence of any of the aforementioned diagnoses (Geiger et al, 2010).

Figure 126-7. Society for Fetal Urology (SFU) criteria as demonstrated in postnatal sonograms. Grade 0 shows no central renal dilation; grade 1, renal pelvis only is visible; grade 2, major calyces can be identified; grade 3, major and minor calyces can be identified; and grade 4, features of grade 3 are present but with parenchymal thinning as well. Within grade 3, there are many different degrees of collecting system dilation that conform to the criteria.

Figure 126-8. A, Renal sonogram demonstrating hydronephrosis and hydroureter associated with a mid-ureteral calculus. B, “Twinkling” artifact seen by color Doppler application to a renal calculus.

Pediatric testicular and paratesticular masses must be viewed in conjunction with the patient’s age and complete clinical picture but are generally well characterized by ultrasonography (Delaney and Karmazyn, 2013). The most common prepubertal primary testicular tumor is benign teratoma characterized by a heterogeneous mass with areas of solid, cystic, and calcified components (Pohl et al, 2004). Yolk sac tumor is a homogeneous well-vascularized mass (Fig. 126-13). An epidermoid cyst has the unique appearance of hyperechoic and hypoechoic rings or “onion rings” with no internal blood flow (Delaney and Karmazyn, 2013) (Fig. 126-14). In the setting of congenital adrenal hyperplasia, bilateral hypoechoic, hyperemic, heterogeneous adrenal rests can be seen in children who have inappropriate steroid replacement or poor compliance. Scrotal masses and their appearance are discussed in detail in Chapter 156.

Ultrasonography in the evaluation of routine cryptorchidism should not be pursued (American Urological Association, 2013). Multiple studies have confirmed its poor sensitivity in detecting and localizing the undescended testicle, and ultrasonographic findings do not alter the necessary treatment plan (Tasian and Copp, 2011). A reasonable exception would be cryptorchidism in an obese child who is difficult to examine, where the presence of an inguinal testis on sonography would simplify the surgical approach. Ultrasonography is the primary imaging modality in the setting of ambiguous genitalia or severe hypospadias with nonpalpable gonads for detection of müllerian structures, which can guide subsequent workup (Chavhan et al, 2008).

Magnetic Resonance Imaging

Upper Tract

MRI is generally used to characterize complex congenital anomalies when sonography cannot provide sufficient detail. It is not as helpful in the setting of infection, stones, or trauma. Precontrast MRI series may be sufficient to diagnose or confirm other congenital

anomalies with great detail such as ectopic ureters, renal duplication anomalies, renal cysts, and calyceal diverticula. Cost, accessibility, and need for sedation in young children limit its overall use.

In the evaluation of hydronephrosis, magnetic resonance urography is a plausible alternative to diuretic renography with far superior anatomic resolution and no radiation exposure. The detailed imaging can provide pinpoint localization of anatomic abnormalities, differential function, and assessment of drainage that can assist in surgical planning. Protocols and formulas have been developed to determine renal function and assess drainage (Jones et al, 2004). Many different protocols have been developed but are similar to those used in mercaptoacetyltriglycine (MAG3) diuretic renography. The contrast medium used is gadolinium-based. The child should be well hydrated, and furosemide (1 mg/kg; maximum 40 mg) is given. Timing of the furosemide administration, bladder catheterization, and patient positioning vary by protocol (Vivier et al, 2010a; Darge et al, 2013). Precontrast T2 sequences are obtained first followed by three-dimensional T2 sequences with fat saturation and 1-mm slice thickness. The contrast medium is slowly injected, and a T1 fat-saturated dynamic scan is continued until contrast medium has filled the ureters (Darge et al, 2013). Widespread adoption of this method has been limited because it requires complex post-processing by a clinician specialized in these techniques. It is possible to use free programs such as CHOP-fMRU (www.chop-fmru.com) or Image J (National Institutes of Health) to assist in generation of the functional analysis (Khrichenko and Darge, 2010; Vivier et al, 2010b). Its application in children is promising, but studies to confirm its equivalence to diuretic renography and widespread education on interpretation are still needed (Perez-Brayfield et al, 2003; Grattan-Smith and Jones, 2006).

Lower Tract and Genitalia

MRI can be used to evaluate the lower urinary tract but rarely with better sensitivity than a well-performed sonogram. The bladder can be seen quite well and usually is included in the series described

Figure 126-9. Sonographic example of an infant found to have posterior urethral valve. A and B, Images of the kidneys demonstrate echogenic renal parenchyma, moderate to severe hydronephrosis, and renal cortical cyst (upper pole left kidney). C, Image of the bladder demonstrates significant distal hydroureter bilaterally.

earlier for the upper tract. In the setting of disorders of sexual differentiation, sonography and urogenitography are typically the only studies needed for diagnosis and surgical planning. Sensitivity and specificity of MRI compared with sonography for identification of internal structures including gonadal detection are marginally

better at best (Gambino et al, 1992; Biswas et al, 2004; Mansour et al, 2012).

IONIZING MODALITIES

Conventional Radiography and Fluoroscopy

Upper and Lower Tract

Intravenous pyelography has fallen out of favor with the advent of the other modalities offering high-resolution anatomic studies and predictably reproducible functional studies. Intravenous pyelography consists of multiple sequential radiographs throughout the excretion and drainage of contrast material and in different focal planes to obtain anatomic and functional information. On a well-performed study, accurate localization of obstructive lesions and radiopaque stones can be seen. Drainage time can also be assessed, although not as precisely as in diuretic renography.

Retrograde pyelography involves injection of contrast medium into the ureteral orifice; this procedure requires anesthesia in a child. Retrograde pyelography is best used for intraoperative localization of an obstructive lesion identified preoperatively using other studies. However, free retrograde flow cannot be assumed to equate to free, unobstructed antegrade flow and vice versa, especially after a prior surgical repair. For example, small postsurgical tissue flaps can cause obstructed antegrade flow but give an unobstructed appearance on retrograde pyelography.

Plain abdominal radiography or a kidney-ureter-bladder film is used not only for detection of radiopaque stones but also for evaluation of constipation in children with voiding dysfunction. Few data support the accuracy of plain films in detecting or evaluating treatment for constipation (Reuchlin-Vroklage et al, 2005; Berger et al, 2012). However, radiography provides impressive visual evidence for parents who are dubious of the diagnosis of constipation despite the child's clinical signs and symptoms, which leads them to support treatment.

Fluoroscopic VCUG, also referred to as a micturating cystourethrogram, provides information on the lower urinary tract and, in the setting of VUR, valuable upper tract information as well. VCUG is an excellent high-resolution anatomic study of the bladder and urethra but can also provide valuable functional data with regard to bladder emptying. VCUG can be used to detect abnormalities of the bladder wall (e.g., trabeculation, ureterocele, diverticulum, bladder neck hypertrophy, tumors), urethra (e.g., posterior urethral valve, urethral stricture, diverticulum), bladder stones, bladder rupture, and foreign bodies (Figs. 126-15 and 126-16). The initial scout film can also identify many spinal abnormalities.

Cystourethrography has been delayed between 4 and 6 weeks after UTI, when it is indicated, on the premise that early VCUG might demonstrate mild transient VUR created by inflammatory changes at the trigone. However, because it is rare for clinically significant VUR present during infection to disappear after treatment and because the identification of even transient VUR during UTI might be clinically meaningful, a prolonged waiting period is unnecessary (Gross and Lebowitz, 1981; Craig et al, 1997). If VUR is detected on VCUG performed early in the course of febrile UTI, it should be considered that ureteral dilation caused by endotoxin overestimates the degree of VUR (Roberts, 1975; Hellström et al, 1987). Positional instillation of contrast cystography is used sparingly with good effect for diagnosis of occult VUR in selected children with negative VCUG but persistent febrile UTIs despite treatment of all other potential etiologies (Rubenstein et al, 2003; Hagerty et al, 2008b). The reliability of positional instillation of contrast cystography to unmask only clinically significant occult VUR is debatable. To avoid overtreatment, it should be used only as a last resort in patients with complicated febrile UTI. However, it is important to perform the test properly with passive instillation of contrast medium at a height of 1 meter above the bladder as

Figure 126-10. Sonographic images of the bladder reveal ureterocele (A), diverticulum (B), and large calculi with “twinkling” artifact (C).

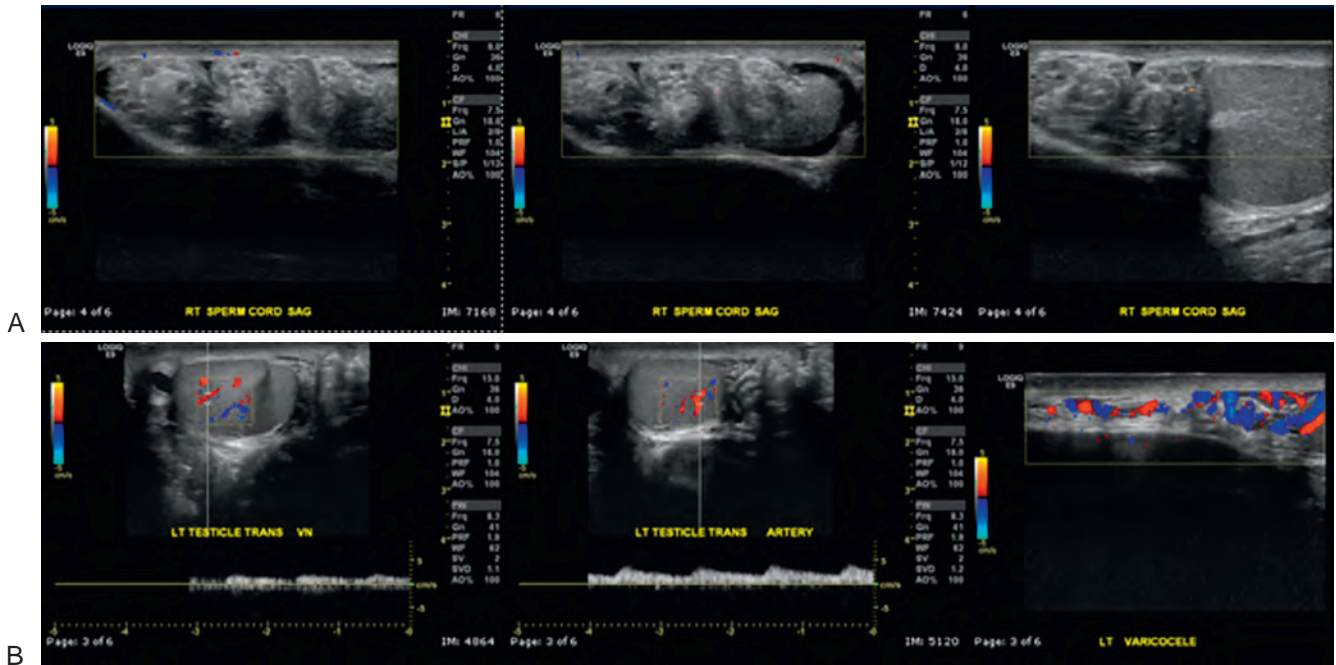

Figure 126-11. Scrotal sonogram in a 19-year-old man with acute onset of right testis pain. Doppler sonography (A) shows the “whirlpool” sign, which has been associated with torsion of the spermatic cord. Doppler sonography did not identify flow, as compared with the left testis (B), which demonstrated ample flow in the nontorsed cord and testis. An incidental left varicocele was noted as well.

Figure 126-12. Scrotal sonogram in a 13-year-old boy with acute onset of left scrotal swelling showing hyperemia of the left epididymis consistent with epididymo-orchitis.

Figure 126-13. Scrotal sonogram in a 2-year-old boy for an enlarged right testis (A), ultimately found to be a yolk sac tumor. For comparison, the normal left testis (B) is shown.

Figure 126-14. Testicular lesion with no internal blood flow and hyperechoic features found to be an epidermoid cyst.

originally described to avoid creation of purely iatrogenic VUR (Hagerty et al, 2008a).

Genitalia

Urogenitography can provide essential information for surgical planning and classification of patients with disorders of sexual differentiation. Typically, a catheter is placed within the single perineal opening, and contrast medium is injected under fluoroscopy to identify the confluence of urethral and vaginal structures as well as their orientation. Alternatively, a Foley catheter can be used with the balloon inflated and pressed up to the perineum with the tip in the perineal opening for retrograde filling (Chavhan et al, 2008).

The findings of urogenitography can be classified based on Shopfner's classification scheme (Shopfner, 1964) (Fig. 126-17).

Computed Tomography

Upper Tract

The role of CT in children is based less on its diagnostic capabilities than on its availability and quick acquisition time. This advantage is best realized in cases of blunt abdominal trauma and polytrauma. However, with advances in sonography and MRI, the need for CT in pediatric patients at the cost of potentially harmful radiation exposure is dwindling. CT has little role in the evaluation of pediatric hydronephrosis because it offers little advantage over ultrasonography with unwanted ionizing radiation. Similar to ultrasonography, it is a detailed anatomic study but with the ability to imply function in noncalcareous hydronephrosis with the addition of intravenous contrast medium and delayed images. Although a delayed nephrogram and ureteral drainage compared with the contralateral side signals obstruction, this is difficult to quantitate. CT can give detailed anatomic information in the setting of renal and ureteral anomalies in more complex patients (e.g., ectopic kidney, ectopic ureter, megaureter, duplication anomalies, renovascular anomalies), which may be helpful in surgical planning when sonography or MRI is inconclusive or unavailable. Likewise, CT has a limited role in the setting of childhood UTI and is best reserved for situations in which nonionizing modalities are inconclusive. MRI and CT can be helpful in assessing infections related to renal abscess, extraurinary fistulization, postoperative complications, or urinary obstruction (Fig. 126-18). The most obvious advantage of CT is in the detection of urolithiasis. CT is better than sonography at detecting and quantifying stone burden; however, it has been shown that this increased accuracy seldom has a clinical impact (Passerotti et al, 2009). Care should be taken to follow the ALARA principle when choosing to use CT in all patients, but especially in children with stone disease, who will likely have a lifetime of frequent imaging episodes.

Figure 126-15. Various findings on voiding cystourethrography. A, Highly trabeculated bladder. B, Ureterocele within bladder (*left*) and everting (*right*). C, Large bladder diverticulum and elongated posterior urethra in child with posterior urethral valve. D, Elongated posterior urethra secondary to posterior urethral valve and bilateral grade 5 vesicoureteral reflux. E, Short distal bulbar urethral stricture.

Figure 126-16. A 15-year-old girl with a pelvic fracture underwent a screening computed tomography scan that suggested a bladder injury, which was confirmed by contrast cystography. Note the extreme elevation of the bladder neck ("pie-in-the-sky") on the cystogram and clear demonstration of contrast medium collecting in the retroperitoneal space.

Figure 126-17. Genitogram of an infant girl with 46,XX ovotesticular disorder of sex development showing a low confluence of the urethra and vagina and reflux into the right fallopian tube. This is consistent with a Shopfner type III classification.

Figure 126-18. A 6-year-old boy presented with abdominal pain, elevated erythrocyte sedimentation rate and C-reactive protein, and inability to stand erect. **A,** Sonogram of the kidneys with Doppler views demonstrates a heterogeneous collection in the lower pole of the left kidney. **B,** On computed tomography scan, this region is confirmed as a renal abscess.

Lower Tract and Genitalia

CT of the lower tract and genitalia is typically reserved for detection of bladder or pelvic trauma. CT cystography can be performed either by antegrade/delayed filling or retrograde filling with a catheter to detect bladder or bladder augment rupture. Complete filling of the bladder with contrast medium is necessary to avoid missing small leaks secondary to insufficient intraluminal pressure or gravitational settling of contrast medium on the opposite side of the perforation. Although filling of the bladder with contrast medium could be performed with a conventional cystogram, CT can provide better anatomic resolution and immediate classification of such rupture as intraperitoneal or extraperitoneal, which would affect management options.

Nuclear Medicine

Renal Cortical Scintigraphy

Renal cortical scintigraphy using technetium-99m (^{99m}Tc)-DMSA relies on uptake by proximal tubular cells, a process that is dependent on renal blood flow (Majd and Rushton, 1992). Focal renal blood flow is decreased in sites of acute pyelonephritis, which corresponds to areas of relative photon deficiency seen on DMSA scans (Rushton and Majd, 1992). Although acute pyelonephritic lesions appear as areas of decreased peripheral uptake with preservation of the reniform contour, renal scars can be differentiated based on observation of volume loss, which interrupts the normal reniform outline, resulting in a concavity. These lesions can be focal, multifocal, or diffuse. Although it is possible for an experienced observer to distinguish between acute and chronic lesions, differentiation is frequently difficult in kidneys with acute pyelonephritis superimposed on preexisting renal scars. Using histopathologic criteria in a piglet autopsy study of induced acute pyelonephritis, sensitivity of DMSA for acute pyelonephritis was 87%, and specificity was 100% (Rushton et al, 1988). A similar experiment demonstrated slightly higher sensitivity with lower specificity but equivalent diagnostic accuracy when using single photon emission computed tomography detection compared to planar (pinhole) detection (Majd et al, 1996).

The timing of DMSA scintigraphy is determined by whether one is seeking to document the acute inflammatory changes of pyelonephritis or irreversible renal cortical scarring. Because inflammation is a transient process, acute changes are reliably seen when the DMSA scan is obtained within days of the acute episode and gradually resolve over the next 5 months such that by 6 months any lesion demonstrated on scintigraphy is likely a fixed scar (Stokland et al, 1996a, 1996b; Ghasemi et al, 2013). Acute DMSA scan lesions persist in 36% to 52% of kidneys (Rushton and Majd, 1992) (Fig. 126-19).

Diuretic Scintigraphy

The gold standard for differentiation of obstructive and nonobstructive hydronephrosis and hydroureter is diuretic renography. This imaging is accomplished with either ^{99m}Tc -diethylenetriamine-pentaacetic acid (DTPA) or, more commonly, ^{99m}Tc -MAG3. A strict protocol should be followed to ensure accurate and reproducible results (Majd, 1989; Conway and Maizels, 1992; Shulkin et al, 2008). The clinician should review the actual drainage images, regions of interest used, and curves because any variation in technique can lead to misleading results.

There are three key elements to successful diuretic renography: hydration, bladder drainage, and timing of diuretic administration. Ideally, an intravenous line is placed for hydration before the study in addition to encouragement of oral hydration before arrival for the study. Poor hydration or poor renal function can lead to false-positive results owing to a slow uptake curve and poor diuretic response. For this reason, it is best to wait until the child is at least 1 month old. A catheter is helpful in eliminating any concerns of bladder filling affecting upper tract drainage; difficult interpretation secondary to VUR, hydroureter, or voiding dysfunction; and increased gonadal radiation exposure secondary to radioactive urine (Mandell et al, 1997).

Intravenous furosemide (1 mg/kg) is ideally given when the dilated collecting system is determined to be maximally filled; however, timing of diuretic administration is largely institution specific. Other common protocols give the diuretic 20 minutes after injection of the tracer (F+20), right after the tracer (F+0), or 15 minutes before the tracer (F-15). Although we prefer the "Well

Figure 126-19. A and B, Dimercaptosuccinic acid renal scans in two different patients demonstrating areas of photopenia with preservation of the renal contour consistent with acute pyelonephritis. A, Formation of a renal scar is demonstrated, which can be differentiated from the acute lesion because of loss of the renal contour. B, Complete resolution of all areas of acute pyelonephritis is demonstrated after 6 months.

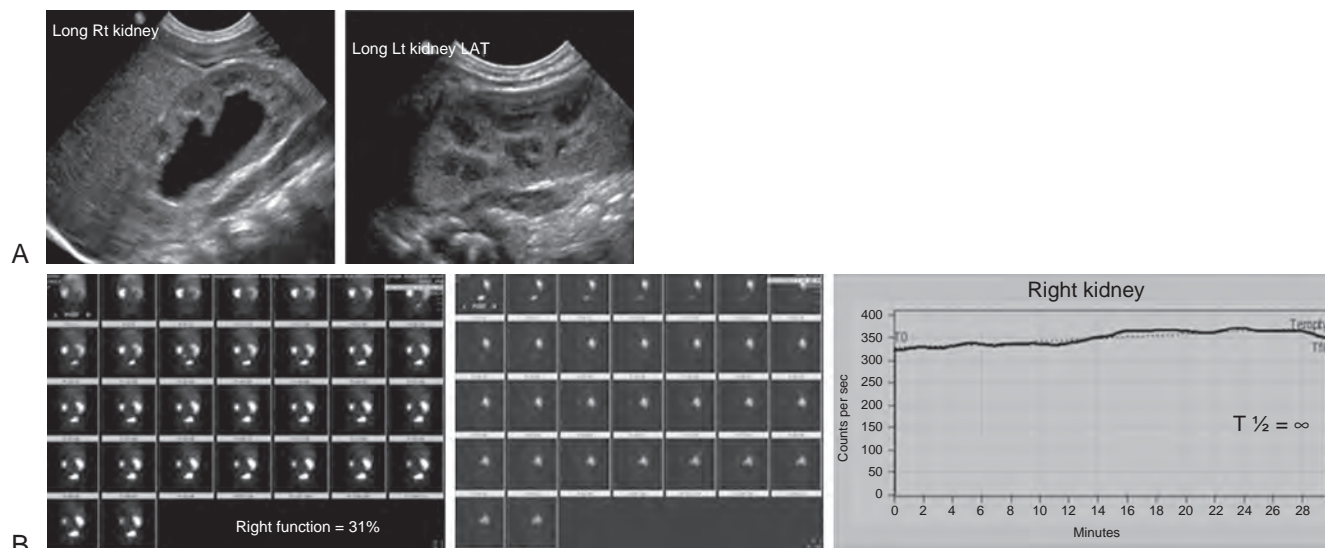

Figure 126-20. A, Renal sonogram demonstrating grade 3 hydronephrosis (mostly intrarenal dilation) without hydroureter. The left kidney is normal. B, ^{99m}Tc -Mercaptoacetyltryglycine furosemide renal scan showing high-grade ureteropelvic junction obstruction with reduced renal function from the right kidney (31%). The diuresis curve demonstrates no drainage and instead reflects continuous accumulation of tracer in the right collecting system.

Tempered" approach, it requires active participation of an experienced technician or radiologist (Conway and Maizels, 1992). The F+0 approach has shown reliable results in children with less experience needed, but it may be more difficult to interpret in slow-filling, capacious collecting systems (Wong et al, 1999). It is important to know which protocol is being used to interpret the test accurately and/or compare with previous studies. During the diuretic phase, the region of interest should be drawn around the collecting system, including the ureter only in cases of hydroureter. After completion of the diuretic phase recording, the child should be held upright for 5 minutes and allowed to void if no catheter was used. A repeat image is captured to assess residual activity after gravity-assisted drainage. Differential renal function, washout curves, and washout half-times can be computer-generated for proper interpretation of the test (Shalaby-Rana et al, 1997).

Management decisions are based on renal function, radiotracer washout half-time, shape of the washout curve, and gravity-assisted drainage. In contrast to adults, in children there are no established washout half-times that define an obstructed or unobstructed state. The washout curve is typically more revealing than the absolute half-time values, especially in young children or children after pyeloplasty in whom a dilated system may be slow to drain but not obstructed. A curve that initially slopes downward but then levels off or starts to rise (Homsy sign) is a sign of intermittent hydronephrosis secondary to the diuretic response but not indicative of obstruction (O'Reilly et al, 1996). These biphasic curves warrant further observation. In cases of equivocal washout curves, gravity-assisted drainage of less than 50% residual activity can be used to confirm obstruction (Wong et al, 2000). All the information acquired from the scan must be used to determine the proper management instead of one parameter in isolation (Figs. 126-20 to 126-24).

Radionuclide Cystography

Direct radionuclide cystography can be accurately used for detection of VUR with greater sensitivity and lower radiation

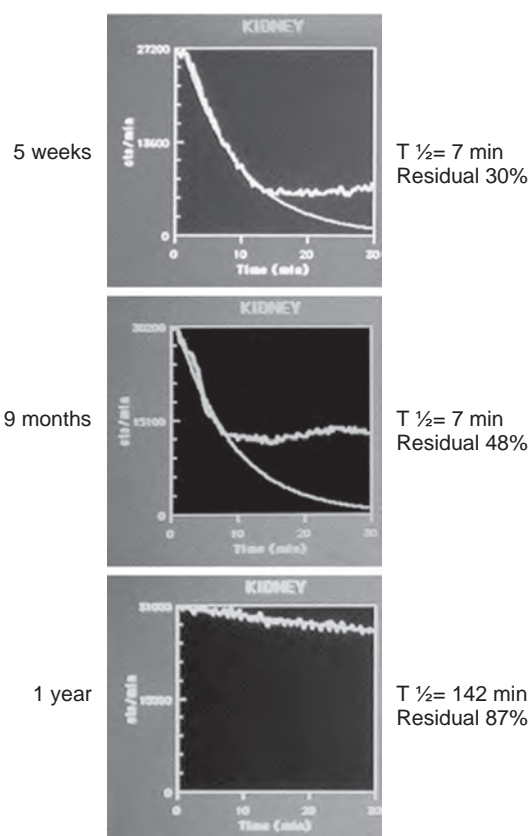

Figure 126-21. A single diuresis renogram may not be sufficient to exclude obstruction. In this example, three consecutive ^{99m}Tc -mercaptoacetyltryglycine diuresis renograms on the same patient demonstrate progressively poor drainage (prolongation of the half-time [$T_{1/2}$] and retention of tracer).

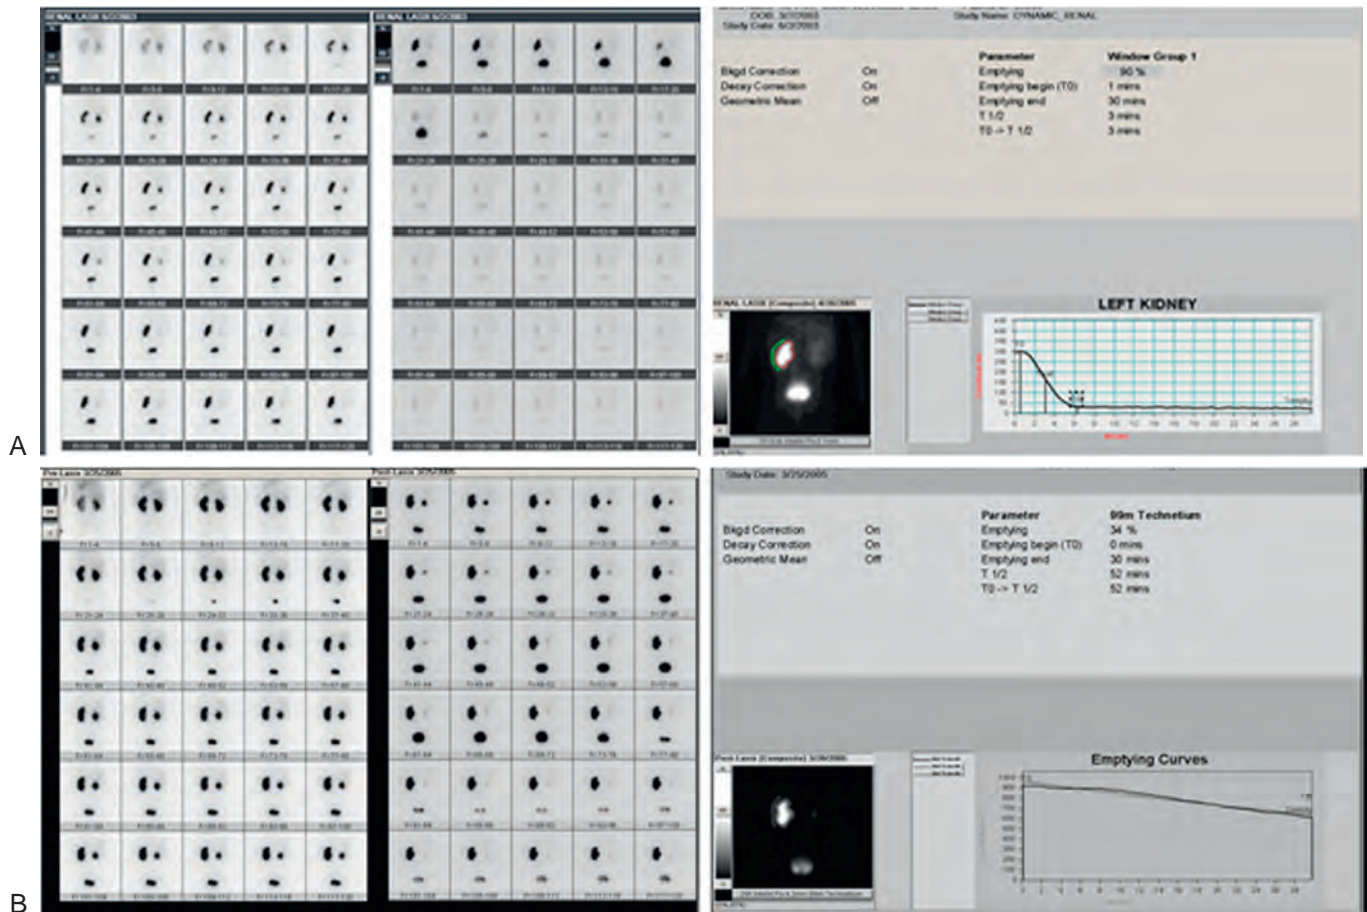

Figure 126-22. A and B, ^{99m}Tc -Mercaptoacetyltryglycine diuresis renograms performed on a 3-month-old infant with prenatally detected hydronephrosis. The dilated right collecting system appears to drain well initially (A), but on repeat renography at 2 years of age (B) demonstrates a prolonged half-time. Based on these findings, this child was managed with a pyeloplasty.

exposure than standard VCUG (Brown et al, 2000; Sukan et al, 2003; Unver et al, 2006). However, it lacks the anatomic resolution of the collecting system and urethra, still requires urethral catheterization, and is still a nonphysiologic measurement. Exact grading comparisons with VCUG can be difficult but are possible (Fretzayas et al, 1984; Zhang et al, 1987; Polito et al, 2000; Unver et al, 2006). Indirect radionuclide cystography can be performed without catheterization after radionuclide renography and provides a non-invasive, physiologic test, but it is not as sensitive as direct methods and so it is not routinely used to detect VUR (Bower et al, 1985) (Fig. 126-25).

Radionuclide Testicular Scanning

Testicular scintigraphy has been around since the 1970s and is typically promoted to distinguish between testicular torsion and inflammatory conditions of the testicle (e.g., epididymitis, orchitis, testicular appendage torsion) (Holder et al, 1981). The test is performed by intravenous injection of ^{99m}Tc pertechnetate followed by dynamic and static gamma images of the pelvis. Similar to renal scintigraphy, photon-deficient areas represent poor blood flow as in torsion, and photon-hyperdense areas can represent inflammation as in epididymitis. In

KEY POINTS

- The ALARA principle should be followed when considering imaging in children.
- A normal infant renal sonogram can be confused with mature hydronephrosis because of hypoechoic renal pyramids with a distinct corticomedullary junction.
- A normal sonogram is insufficient to risk stratify a child with acute pyelonephritis and is not a good predictor of VUR.
- Ultrasonography should not be performed for routine evaluation of cryptorchidism.
- CT and MRI may require sedation in a young child, and less intensive modalities should be used if possible.
- Diagnosis of obstruction in children with diuretic renography requires review of all parameters of the test because variations in technique can skew results considerably.

experienced centers, this technique can be very sensitive and specific (up to 100%) and potentially perform better than sonography in the setting of an acutely painful scrotum (Mendel et al, 1985; Flores et al, 1996; Wu et al, 2002). However, its lack of availability, invasiveness, and radiation

Figure 126-23. Ultrasound scan shows mild right hydronephrosis in a 7-year-old boy with right upper quadrant pain. A, Diuresis renogram shows nonobstructive drainage. The patient presented a second time with pain. This time, the sonogram showed increased dilation of the right collecting system. B, Diuresis renogram demonstrates worse drainage, and the patient reported pain after furosemide (Lasix) administration. C, After pyeloplasty, renography shows prompt spontaneous drainage; furosemide was not administered. T $\frac{1}{2}$, half-time.

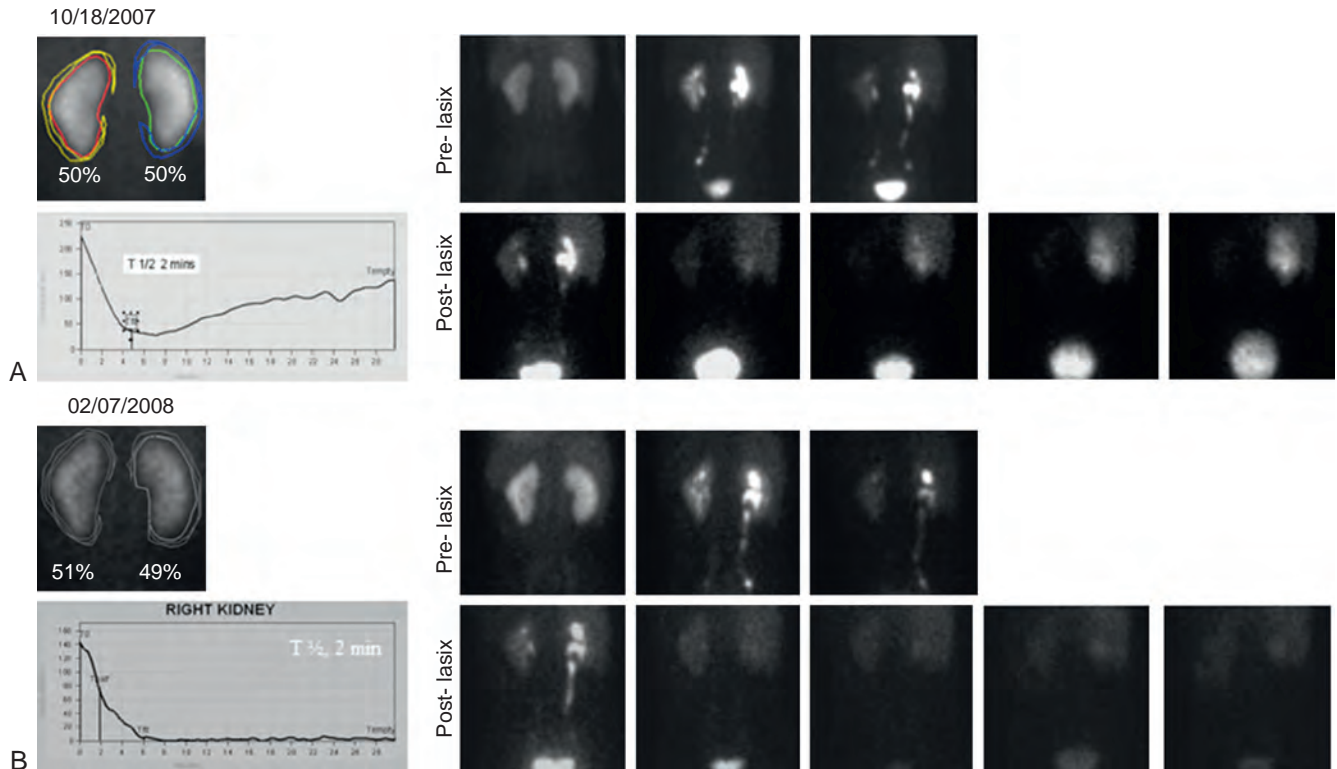

Figure 126-24. A, Initial diuresis renogram shows mild right hydronephrosis. After administration of furosemide (Lasix), there was rapid clearance of the tracer from the pelvicalyceal system with the washout half-time ($T_{1/2}$) of 2 minutes. A few minutes later, the patient developed right flank pain, and there was gradual accumulation of the tracer in the right kidney (rising second part of the curve) (A). B, Postoperative differential renal function remained stable, and drainage improved significantly.

Figure 126-25 Radionuclide cystography examples of mild (A), moderate (B), and severe (C) vesicoureteral reflux.

exposure limit its widespread adoption over ultrasonography. Perhaps the most appropriate use of testicular scintigraphy is in cases that are equivocal by examination and sonogram, but only if potentially testicle-saving surgery is not unreasonably delayed (Kodali et al, 2013).

127 Infection and Inflammation of the Pediatric Genitourinary Tract

Christopher S. Cooper, MD, FAAP, FACS, and Douglas W. Storm, MD, FAAP

Evaluation and Management of a Child with a Fever

Classification of Pediatric Urinary Tract Infections

Diagnosis of Pediatric Urinary Tract Infection

Management of Pediatric Urinary Tract Infection

Management of Post-Urinary Tract Infection

Sequelae of Pediatric Urinary Tract Infections

Uncommon Pediatric Urinary Tract Infections

Data from the Urologic Disease in America Project demonstrate just how significant a burden pediatric urinary tract infections (UTIs) are to the American public. This study indicates that 2.4% to 2.8% of all American children are affected annually by a UTI and these infections account for 1.1 million medical visits per year (Freedman, 2005). In addition, inpatient hospital costs alone for treatment of children admitted with pyelonephritis total more than \$180 million per year in the United States (Freedman, 2005).

UTIs are epidemic in children, but not all UTIs are the same. Some children have a single, sentinel UTI, whereas others suffer recurrent infections in infancy and into childhood and beyond. Some UTIs are associated with fever, and others only cause lower urinary tract symptoms or malodorous urine. Some UTIs lead to renal scarring, hypertension, and/or end-stage renal disease whereas others present no long-term sequelae. Unfortunately, at this time, there is no definitive way to predict whether a child will ever develop a UTI, to determine if they will develop further UTIs, or to determine if they will suffer long-term medical issues related to their infections. This chapter describes the pathogenesis, evaluation, and management of pediatric UTIs to facilitate the care provider's individualized management decisions for each child.

EVALUATION AND MANAGEMENT OF A CHILD WITH A FEVER

Infants and young children will frequently present to health care providers with the history of fever of undetermined etiology. Although an extensive discussion of the workup and management of febrile infants is beyond the scope of this chapter, it is important for all pediatric care providers to have a basic knowledge of the care of these patients. For children, a clinically significant fever is generally defined as a rectal temperature of 100.4° F (38° C) or higher (Sur and Bukont, 2007). In a previously healthy child 3 to 36 months of age, a temperature of 39° C or higher warrants further evaluation (Baraff et al, 1993; Baraff, 2000; American College of Emergency Physicians Clinical Policies Committee, 2003). In the vast majority of these children, the source of their fever will be a viral illness; however, 7% to 13% of these children, with no clear fever source, present with occult bacteremia and serious bacterial infections (Dagan et al, 1988; Baraff, 2000; Kadish et al, 2000). Serious bacterial infections in these patients include bacteremia, bacterial gastroenteritis, cellulitis, meningitis, osteomyelitis, pneumonia, septic arthritis, and UTIs. These infections are more common in children younger than 90 days and especially in children younger than 29 days. In children younger than 90 days, 7.2% experience a

serious bacterial infection, whereas 8.7% to 13% of children younger than 29 days will have such a serious infection (Baraff et al, 1993; Baker and Bell, 1999).

The goal of evaluating the febrile child is to ensure that serious infections are not missed and that proper treatment is initiated quickly. A summary of the evaluation and treatment of a child with a rectal temperature higher than 38° C is provided in Figure 127-1. In such an evaluation, the ability to detect a child appearing “toxic” is important, as these patients show a higher rate of serious infections. Signs and symptoms of toxicity include cyanosis, decreased activity, hyper- and hypoventilation, inability to interact with parents, irritability, lethargy, poor tone, poor perfusion, tachycardia, and poor eye contact (Sur and Bukont, 2007). It is important to keep in mind that although toxic appearance, age younger than 30 days, and rectal temperature of 39.4° C or greater are highly predictive of bacteremia, not one of these features guarantees the identification of a child with a serious bacterial infection, and absence of these features also does not rule out a serious infection (Pantell et al, 2004).

As will be discussed in more detail later in this chapter, the diagnosis of a UTI in children can be difficult because the symptoms can be nonspecific. In children aged 0 to 24 months, the presence of a fever higher than 40° C, history of a previous UTI, suprapubic tenderness, and uncircumcised penis are the most useful signs and symptoms in predicting a UTI in a febrile child (Shaikh et al, 2007). Other factors such as vomiting, diarrhea, poor feeding, and irritability are not sensitive or specific in screening for the presence of a UTI (Shaikh et al, 2007). In children older than 24 months, who are more verbal, the more classic symptoms of abdominal pain, back pain, dysuria, urinary frequency, and new-onset urinary incontinence are all predictive of UTI (Shaikh et al, 2007). One must have a high degree of suspicion and have an understanding of the possible causes of fever, especially in very young children, to diagnose the cause of the infection. UTIs are common, accounting for 7% of febrile infections in infants and 7.8% of febrile infections in children older than 24 months (Shaikh et al, 2008).

KEY POINTS: DIAGNOSIS OF URINARY TRACT INFECTION IN A CHILD

- Signs and symptoms of a UTI in young children may be nonspecific.
- UTIs are common in febrile infants.
- Children who appear toxic on evaluation require special attention.

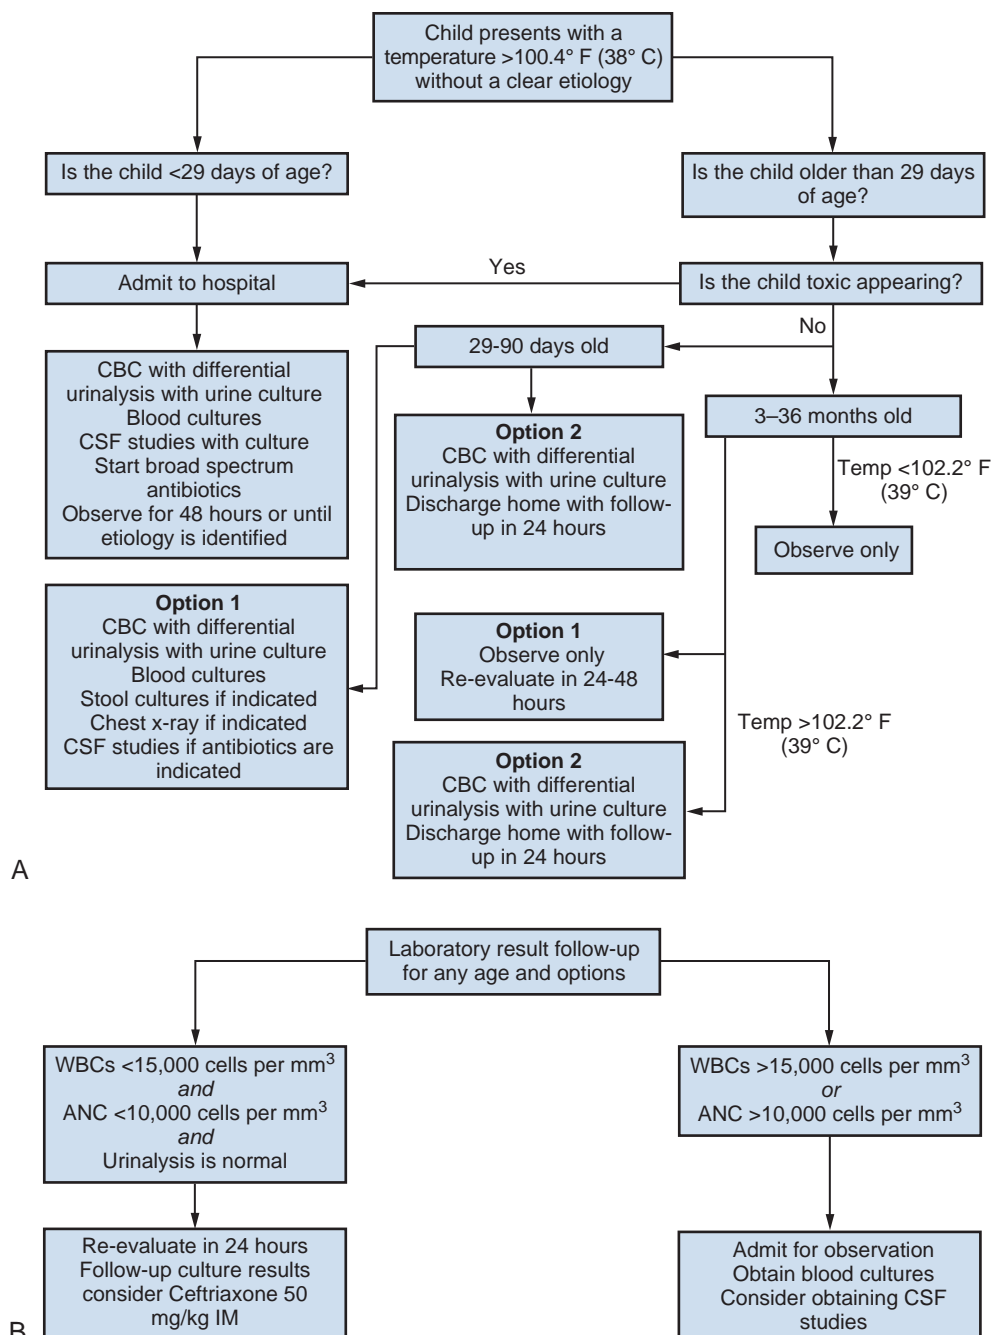

Figure 127-1. A, Algorithm for the treatment of a child aged 0 to 36 months with a fever higher than 100.4° F (38° C) with no etiology for the fever. B, Continued considerations for the treatment of a child aged 0 to 36 months with a fever higher than 100.4° F (38° C) with no etiology for the fever. ANC, absolute neutrophil count; CBC, complete blood count; CSF, cerebrospinal fluid; IM, intramuscular; WBCs, white blood cells.

Definition of a Urinary Tract Infection

What constitutes a “significant” clinical UTI in a child is somewhat controversial. Urine is normally sterile, so the presence of bacteria in a urine specimen begins to define whether a UTI is present. As will be discussed in more detail later in this chapter, the number of colony-forming units (CFU) per mL of urine used to define a UTI varies according to different criteria as well as by the method of collection. If a suprapubic aspiration was performed, then by some criteria recovery of any organisms defines a UTI. For catheterized specimens, recovery of at least 50,000 CFU/mL is required to define a UTI and 100,000 CFU/mL are required if the specimen was collected via a clean-catch method (Hoberman et al, 1994). These

different values in conjunction with the patient’s symptoms help define the likelihood of a true UTI.

Pathogenesis of Urinary Tract Infection Development in Children

The factors that contribute to UTI development in children are not yet completely understood. Host features, bacterial characteristics, and immune status all contribute to the development of pediatric UTIs. The role that factors from each of these areas play in pediatric UTI development is difficult to pinpoint, as these influences are in a constant state of flux, particularly in children. For instance,

immunity and gastrointestinal bacterial colonization are completely different in a newborn as compared to a 6-month-old child. In addition, host features such as circumcision status and toilet training may influence and change a child's risk of UTI development. In this section, we describe the current understanding about how factors from these different areas contribute to UTI development in children.

Bacterial Factors Leading to Pediatric Urinary Tract Infections

Bacteria may be divided into commensal and virulent bacteria. The term *virulence* comes from the Latin word for poisonous, *veneficus*, and is defined as the ability of an organism to cause disease in a host. Virulent bacteria that cause UTIs are otherwise known as uropathogenic bacteria. Virulent bacteria possess different adaptations and fitness factors that allow them to subvert or hijack host defenses and reside in an environment where they would not normally reside (Johnson, 1991; Stapleton, 2014). These virulence mechanisms allow the bacteria to attach initially to urogenital mucosal surfaces and then to interact with these tissues by setting off cascades of signaling and other immunologic response events and subsequently invade the bladder (Stapleton, 2014). Commensal bacteria may also cause UTIs, but commensals are defined by lacking the virulent traits that would allow bacteria to subvert a host's immune defenses.

Escherichia coli is the most commonly studied UTI-causing organism, as it is by far the most common bacterial UTI pathogen. Of the UTIs caused by *E. coli*, 80% are triggered by uropathogenic (virulent) *E. coli* (UPEC), whereas 20% of the *E. coli* causing UTIs are classified as commensal organisms (Krieger, 2002; Bien et al, 2012). This reflects the importance of virulence factors in UTI development. Virulence factors include properties that improve bacterial adherence to uroepithelial cells, properties that allow bacterial nourishment in otherwise adverse environments, properties that protect bacteria from the host's immune response, and toxins that allow bacteria to invade host cells (Fig. 127-2).

Figure 127-2. Schematic representation of an *E. coli* cell interacting with host tissue, highlighting features relevant to bacterial pathogenicity. Solid black circles, triangles, and rectangles indicate membrane proteins involved in transport, serum resistance, and so forth. CM, cystoplasmic membrane; LPS, lipopolysaccharide; OM, outer membrane. (Modified from Johnson JR. Virulence factors in *Escherichia coli* urinary tract infection. Clin Microbiol Rev 1991;4(1):80–128. Copyright 1991, American Society for Microbiology.)

Bacterial Fimbriae

Bacterial adherence is perhaps the best understood and is one of the most studied virulence traits. Adherence is considered the first step in UTI pathogenesis with special bacterial structures called *adhesins* mediating this process (Johnson and Stell, 2000; Guyer et al, 2001; Johnson et al, 2001; Schilling et al, 2001; Wullt et al, 2001). These adhesins are also known as pili or F antigens, and they are filamentous appendages that project from the bacterial cells. Fimbrial adhesins can be classified into mannose sensitive, which is more common, or mannose resistant (Krieger, 2002).

The most common mannose-sensitive adhesin is the type 1 fimbriae. Adherence of this fimbriae is blocked by solutions of D-mannose and by concanavalin A (Johnson, 1991). Receptors for type 1 fimbriae are found in the muscular layers but not the epithelium of the human bladder, ureteral epithelium, and kidney cell lines (Korhonen et al, 1981; Virkola et al, 1988; Fujita et al, 1989). Strains of *E. coli*, expressing mannose-sensitive adhesins alone, with no mannose-resistant adhesins, are more commonly associated with patients presenting with clinical symptoms of cystitis and/or asymptomatic bacteria rather than pyelonephritis, suggesting that type 1 fimbriae play a more important role in the colonization and/or infection of the bladder versus contributing to clinical symptoms of pyelonephritis (Brooks et al, 1981; Latham and Stamm, 1984; Gander et al, 1985).

One of the most studied mannose-resistant adhesins is the P fimbriae. These fimbriae were discovered to bind to and agglutinate erythrocytes of the P blood group (Kallén et al, 1980a, 1980b). The binding site for this adhesin appears to be α -galactose-(1-4), a digalactoside in neutral glycosphingolipids found on epithelial cells and red blood cells. The different P blood group antigens and phenotypes that would bind these fimbriae are found in up to 75% of the population (Johnson, 1991). Binding sites have been identified in the human kidney and bladder and isolates expressing P fimbriae have been identified in up to 70% of strains causing clinical symptoms of pyelonephritis (Johnson, 1991).

Other important adhesins that have been identified include S fimbriae, type 1C fimbriae, and O75X adhesions. Each of these has been studied and found to play a role in bacterial adherence, and the different receptors have been found in variable amounts throughout the human genitourinary tract (Table 127-1).

Following bacterial adherence, a signal transduction cascade results in the uptake of bacteria by the bladder's superficial umbrella cells (Fig. 127-3) (Martinez, 2000; Kau et al, 2005). These bacteria enter the bladder's epithelial cells, resulting in the formation of intracellular bacterial communities (IBCs) (Anderson, 2003). During the formation of these IBCs, these normally fast-growing bacteria become much slower and eventually multiply to fill most of the umbrella cell's cytoplasm (Kau et al, 2005). Eventually the bacteria within the IBCs flux out of the host cell, which may allow bacteria to spread within the urinary tract. The bacteria may then re-enter the bladder epithelial cell and form a quiescent reservoir within the cell, which may continue to go unrecognized by the host's immune response, allowing these bacteria to reside within the host and possibly result in recurrent infections (Justice et al, 2004).

Aerobactin

All living cells, including bacteria, need iron. *E. coli* uses iron for oxygen storage and transport, DNA synthesis, electron transport, and metabolism of peroxides (Bagg and Neilands, 1987). As part of the host's response to infection, the amount of available iron is reduced to the invading pathogen by decreasing intestinal absorption, synthesizing additional iron-binding proteins, and shifting iron from the plasma pool into intracellular storage (Johnson, 1991). Therefore, *E. coli* face a considerable challenge in acquiring and meeting their iron needs during an infection. The siderophore aerobactin extracts iron from host iron-binding proteins and then delivers the iron directly to bacterial iron centers (Carbonetti et al, 1986; de Lorenzo and Neilands, 1986; Williams

Curr Opin Microbiol 2005;8:54.)

and Carbonetti, 1986). Bacterial strains with the aerobactin system have a growth advantage in low iron conditions, including the serum and dilute urine.

Hemolysin

The cytolytic protein secreted by most hemolytic *E. coli* is known as alpha hemolysin (Cavaliere et al, 1984). Alpha hemolysin lyses erythrocytes of all mammals and is also toxic to a wide range of host cells contributing to inflammation, tissue injury, and impaired host defenses (Johnson, 1991). In human UTIs, hemolysin production is most common in bacterial strains from patients suffering pyelonephritis as compared to patients with cystitis symptoms.

Capsular Polysaccharide

Capsular polysaccharides, of which *E. coli* has more than 80 types, are linear polymers that coat the bacterial cell, interfering with antigen detection and protecting the cell from host defense detection (Jorgensen et al, 1976). The capsules of most uropathic *E. coli* are composed of group II polysaccharides and are otherwise known as K antigens. Encapsulated K bacterial strains are less well phagocytosed and also have anticomplementary activities, as compared to nonencapsulated strains, which leads to impaired bacterial clearance and complement activation (Howard and Glynn, 1971; Harber et al, 1986). The degree of host defense impairment tends to be proportional to the amount of polysaccharide (Howard and Glynn, 1971). Studies have shown that capsular polysaccharides are poor immunogens in animals and humans, with the K1 polysaccharide yielding a measurable antibody response in only one third of animals immunized with killed K1 bacteria in one study, and another study showing that only 12% of humans suffering pyelonephritis demonstrated an antibody response when the infecting organism was a K1 strain (Kaijser, 1981; Salit et al, 1988). These encapsulated strains have been found to be commonly associated with pyelonephritic UTIs rather than cystitis (Johnson, 1991).

KEY POINTS: BACTERIAL FACTORS

- UTI-causing bacteria may be subdivided into commensal and virulent types; although both cause UTI, virulent organisms cause the majority of UTIs.
- Virulent bacteria possess different adaptations and fitness factors that allow them to subvert or hijack host defenses and reside in an environment where they would not normally reside.
- There are a multitude of bacterial virulence factors that bacteria have, including properties that improve bacterial adherence to uroepithelial cells, properties that allow bacterial nourishment in otherwise adverse environments, properties that protect bacteria from the host's immune response, and toxins that allow bacteria to invade host cells.

Host Risk Factors Leading to Pediatric Urinary Tract Infections

Host factors that seem to affect the incidence of UTI development in children are associated with age, genetics, gender, race, anatomic, functional, and behavioral features.

Gender and Age

The only time that UTIs are more prevalent in boys than in girls is at an age younger than 1 year. At all other ages, even among the elderly, UTIs are far more prevalent in females than in males (Shortliffe and McCue, 2002). About 2.7% of boys, compared to 0.7% of girls, experience a UTI during the first year of life (Winberg et al, 1975). After 1 year of life, the incidence of UTI development drops to 0.03% to 0.2% in males and increases to 1% to 3% in

females (Foxman, 2002). It has been estimated that 7% of girls and 2% of boys suffer a UTI by the age of 6 years (Marild, 1998).

UTIs are common in febrile children, with an incidence of 3% to 5%; however, the risk is greater in girls than in boys after 2 months of age. Females aged 2 months to 2 years with a fever have a relative risk of UTI of 2.27 compared to males (American Academy of Pediatrics, 1999). In older children, especially in sexually active teenagers, there is also a female predominance of UTIs (Ma and Shortliffe, 2004).

Race

UTIs occur in all races, but they appear more commonly in Caucasian girls compared to girls of other races (Keeton and Hillis, 1975; Shaw et al, 1998; Shaw and Gorelick, 1999). In one study evaluating children less than 2 years of age, the authors found that UTIs were the most prevalent in Caucasian children, followed by Hispanic, and then African-American girls, whereas in boys UTIs were more common in Hispanics, followed by Caucasians, and they were least common in African-American boys (Bachur and Harper, 2001). Certainly circumcision status confounds this data, but several studies have shown that African-Americans have fewer UTIs, have lower rates of vesicoureteral reflux (VUR), and may be less likely to develop reflux nephropathy as compared to Caucasians and Hispanics (Kunin, 1968; Lohr et al, 1994; Hoberman and Wald, 1997; Pinto, 2004).

Genetics

Although certain individuals appear to be more prone to developing UTIs, no specific genes have been identified that are linked to developing these infections. Some observations on the occurrence of UTIs, however, lend evidence that there may be a genetic component to UTI development. Children with a history of VUR are still commonly susceptible to UTI development after their reflux resolves (Mansfield et al, 1995; Beetz et al, 2002). In addition, sisters of patients with recurrent UTIs have higher rates of significant bacteriuria compared to the general public (Stauffer et al, 2004). Moreover the two greatest risk factors for women aged 18 to 30 years to develop recurrent UTIs include age at first infection and a mother with a history of UTIs (Scholes et al, 2000).

As previously discussed, P fimbriae are a common virulence factor identified on UPEC. At the time of this adhesin's discovery, glycolipids characterizing the P blood group antigens were found on host uroepithelial cells, acting as bacterial receptors. As it was suspected that individuals with this P blood group phenotype would be more susceptible to UTI development, children with recurrent UTIs were tested for this phenotype. A study by Lomberg and coworkers (1983) identified that 97% of girls with recurrent pyelonephritis expressed the P1 blood group phenotype, in comparison to 75% of controls without UTI.

Other blood group antigens expressed on the urothelial surface also appear to influence UTI susceptibility. These include the ABO, Lewis, and secretor phenotypes. Adult women with Le (a-b-) and Le (a+b+) blood phenotypes are three times as likely to have recurrent UTIs compared to women with the Le (a-b+) phenotype (Sheinfeld et al, 1989). In addition, Jantusch and coworkers (1994) identified that in children with a history of UTIs, the frequency of Le (a-b-) is also increased. In addition, the nonsecretor phenotype of ABH blood group antigens (ABH Ag) has been identified as associated with renal scars seen on ^{99m}Tc-dimercaptosuccinic acid (DMSA) scans in children with VUR and UTIs (Kanematsu et al, 2005).

Circumcision

Multiple studies demonstrate that circumcision reduces the rate of UTI development in the first 6 months of life by almost tenfold (Roberts, 1986; Wiswell et al, 1987; Schoen et al, 2000). This risk appears to correlate with a period during the first 6 months of life when there is an increased amount of

uropathogenic bacteria colonizing the prepuce. This colonization appears to decrease and resolve by 5 years of age (Glennon et al, 1988; Wiswell et al, 1988). In a retrospective review, Wiswell and Roscelli (1986) examined the incidence of UTIs diagnosed by catheterization or suprapubic aspirate (SPA) in more than 200,000 males born in U.S. Army hospitals between 1974 and 1983. They found the UTI incidence in circumcised males was 0.11%, whereas the incidence of infection in uncircumcised males was 1.12%. This compared to an incidence of 0.57% in female children during this study period.

These findings have led to controversy regarding the advantages and disadvantages of routine circumcision in boys. The American Academy of Pediatrics (AAP) Task Force on Circumcision (2012), while weighing the risks and benefits of circumcision in boys (including the prevention of UTIs in neonates), stated that the health benefits of newborn male circumcision outweigh the risks. Although they could not justify routine circumcision in all males, they concluded that the benefits of circumcision are great enough to justify access to this procedure to families choosing it and to warrant third-party payment for the procedure. **However, the question of whether circumcision actually prevents infections later in life continues to be debated in the literature.** Using case-control methods, Singh-Grewal and coworkers (2005) identified that circumcision continues to decrease the rate of UTI development before and after 1 year of age. The degree of risk reduction, however, is dependent on the patient. In a meta-analysis, Singh-Grewal and coworkers (2005) identified that normal, healthy boys have a 0.5% to 1% risk of developing a UTI, and they calculated that approximately 111 healthy boys would need to be circumcised to prevent one UTI. Boys who have a history of recurrent UTIs and those who have high-grade VUR have a 10% and 30% risk of UTI recurrence, respectively (Singh-Grewal et al, 2005). These authors further identified that the number of boys who would need to undergo circumcision in these high-risk groups to prevent a UTI is 11 boys with a history of recurrent UTIs and 4 boys with a history of high-grade VUR.

When evaluating cost data, circumcision also appears to decrease the cost of UTI treatment in boys who develop a UTI who are less than 1 year of age. Schoen and coworkers (2000) identified that not only were uncircumcised males more likely to experience UTIs, but the cost of treating infections in uncircumcised boys was 10 times higher as compared to circumcised patients. This increased cost was accounted for by uncircumcised males developing UTIs at a younger age, and by a greater number of these patients requiring hospital admission to treat their infection. They concluded that newborn circumcision is a valuable preventive health measure and is also a long-term cost-saving measure.

Fecal and Perineal Bacterial Colonization

The vast majority of bacteria causing UTIs enter the bladder via the fecal-perineal-urethral route, whereby bacteria that colonize the gut, perineum, and periurethral area ascend via a retrograde fashion into the lower urinary tract (Stamey and Sexton, 1975; Pfau and Sacks, 1981; Yamamoto et al, 1997). As the saying goes, “you are what you eat,” and we are only beginning to understand the role that the fecal microbiota plays in human disease. **In women who suffer recurrent UTIs, studies demonstrate that the majority of these reinfections are caused by the same strain of UPEC that persists in the fecal microbiota for 12 or more months and circulates through the fecal and vaginal reservoirs to cause recurrent infections** (Russo et al, 1995; Hooton, 2001; Czaja et al, 2009). It is unclear whether the same is true in children suffering from recurrent UTIs, but this certainly could be one mechanism contributing to these pediatric infections.

Studies also demonstrate that women who suffer recurrent UTIs have increased vaginal and periurethral colonization with enteric organisms with concomitant loss of normally predominant and protective vaginal lactobacilli (Hooton et al, 1994; Gupta et al, 1998). **Clinical studies show that women lacking vaginal lactobacilli are at increased risk for vaginal colonization**

with *E. coli*. Exposure to antibiotics, especially trimethoprim-sulfamethoxazole (TMP-SMX), may eradicate these presumably protective lactobacilli (Stapleton, 2014). Whether a similar mechanism predisposes to UTI in children remains to be demonstrated; however, Hansson and coworkers (1989) did show that treatment of schoolgirls for nonurologic infections, usually otitis media, resulted in colonization and bacteriuria with organisms likely to cause a symptomatic infection.

Anatomic Abnormalities

Clearly, anatomic abnormalities of a child's genitourinary system may lead to UTI development. Infections associated with urinary tract malformation will usually appear before 5 years of age (Chang and Shortliffe, 2006). It is important to detect these abnormalities, as many may be surgically correctable, and persistence of these abnormalities may lead to renal damage and/or recurrent infections. Possible anatomic abnormalities include:

- Hydronephrosis
- Ureteropelvic or ureterovesical junction obstruction
- VUR
- Infection stones
- Infected nonfunctional renal segments
- Vesicointestinal or urethrorectal fistulae
- Vesicovaginal fistulae
- Infected necrotic papillae

Given the role that anatomic abnormalities play in pediatric UTI development, the AAP continues to recommend that a renal and bladder ultrasound (RBUS) be performed on all children aged 2 to 24 months after they have experienced their first febrile UTI (Subcommittee on Urinary Tract Infection et al, 2011).

Vesicoureteral Reflux
